First Draft - Comments Welcome

Abstract

This paper considers the evaluation of forecasts of a given statistical functional, such as a mean, quantile, or distribution. Recent work has emphasized the importance of evaluating such forecasts using a loss function that is consistent for the functional of interest, of which there are an infinite number. If the information sets of the competing forecasters are nested and all forecasters produce forecasts that are optimal given their information sets, then the ranking induced by a single consistent loss function is sufficient for ranking by any consistent loss function. However, in the presence of nonnested information sets, parameter estimation error, or misspecified models, the ranking of forecasts may be sensitive to the choice of (consistent) loss function. Moreover, the performance of misspecified forecasting models can differ according to the choice of (consistent) loss function used for parameter estimation. Thus, rather than merely specifying the target functional, which narrows the set of relevant loss functions only to the class of loss functions consistent for that functional, this paper proposes that forecast consumers or survey designers should specify the single specific loss function that will be used to evaluate forecasts. An application to survey forecasts of US inflation illustrates the results.

Keywords: Bregman distance, proper scoring rules, consistent loss functions, point forecasting, density forecasting.

1 Introduction

Recent work in the theory of prediction has (re-)emphasized the importance of the choice of loss function used to evaluate the performance of a forecaster. In particular, there is a growing recognition that the loss function used must "match" the quantity that the forecaster was asked to predict, whether it is the mean, the median, the probability of a particular outcome (e.g., rain, negative economic growth), etc. For example, in the widely-cited "Survey of Professional Forecasters," conducted by the Federal Reserve Bank of Philadelphia, experts are asked to predict a variety of economic variables, with questions such as "What do you expect to be the annual average CPI inflation rate over the next 5 years?" (Section 7 of the survey). In the Thomson Reuters/University of Michigan Survey of Consumers, respondents are asked "By about what percent do you expect prices to go (up/down) on the average, during the next 12 months?" (Question A12b of the survey). The presence of the word "expect" in these questions is an indication (at least to statisticians) that the respondents are being asked for their mathematical expectation of future inflation. The oldest continuous survey of economists' expectations, the Livingston survey, on the other hand, simply asks "What is your forecast of the average annual rate of change in the CPI?," leaving the specific type of forecast unstated.

In point forecasting, a loss function is said to be "consistent" for a given statistical functional (e.g., the mean, median, etc.), if the expected loss is minimized when the given functional is used as the forecast, see Gneiting (2011a) and discussion therein. For example, a loss function is consistent for the mean if no other quantity (median, mode, etc.) leads to a lower expected loss than the mean. The class of loss functions that is consistent for the mean is known as the Bregman class of loss functions, see Savage (1971), Banerjee, *et al.* (2005) and Bregman (1967), and includes the squared-error loss function as a special case. In density or distribution forecasting the analogous idea is that of a "proper" scoring rule, see Gneiting and Raftery (2007): a scoring rule is proper if the expected loss under distribution P is minimized when using P as the distribution forecast. Evaluating forecasts of a given functional using consistent loss functions or proper scoring rules is a minimal requirement for sensible rankings of the competing forecasts.

Gneiting (2011a, p757) summarizes the implications of the above work as follows: *"If point forecasts are to be issued and evaluated, it is essential that either the scoring function be specified ex ante, or an elicitable target functional be named, such as the mean or a quantile of the predictive distribution, and scoring functions be used that are consistent for the target functional."* This paper contributes to this literature by refining this recommendation to reflect some real-word deviations from the ideal predictive environment, and suggests that only the first part of Gneiting's recommendation should stand; specifying the target functional is not generally sufficient to elicit a forecaster's best (according to a given, consistent, loss function) prediction.

Firstly, I show that when two competing forecasts are generated using correctly specified models and the information sets of one of the forecasters nests the other, then the ranking of these forecasts based on a single consistent loss function is sufficient for their ranking using *any* consistent loss function (subject of course to integrability conditions). This is established for the problem of mean forecasting, quantile forecasting (nesting the median as a special case), and distribution forecasting.

Secondly, and with more practical importance, I show that when competing forecasts are based on nonnested information sets, misspecified models, or models using estimated parameters, the ranking of the forecasts is, in general, sensitive to the choice of consistent loss function. Thus, in practice, it is not sufficient to merely specify the statistical functional of interest; rather, the specific loss function that will be used to evaluate the forecasts should be given. This result has large potential implications for survey forecast design and for forecast evaluation more generally.

This result also has implications for the use of multiple loss functions to evaluate forecasts. If the loss functions used are not all consistent for the same statistical functional, then existing arguments from Engelberg, *et al.* (2007), Gneiting (2011a) and Patton (2011) apply, and it is not surprising that the rankings may differ across loss functions. If the loss functions are all consistent for the same functional, then in the absence of misspecified models and nonnested information sets, using multiple measures of accuracy adds *no* information beyond using just one measure. (Note, however, that these loss functions may have different sampling properties, and so careful choice of the loss function to use may lead to improved efficiency.) In the presence of these real-world forecasting complications, using multiple measures of forecast accuracy can lead to clouded results: a forecaster

3

could be best under one loss function and worst under another; averaging the performance across multiple measures could mask true out-performance under one specific loss function.

This paper also shows that if the target variable has a parametric conditional mean function, and the forecaster's model for this is correctly specified, then minimizing the expected loss under *any* Bregman loss function yields a consistent estimator of the model's parameters. However, under misspecification the choice of (Bregman) loss function used in estimation will in general lead to estimators that converge to different probability limits.

The focus in this paper is on applications where the target functional (mean, quantile, etc.) is known, and the task is to find the "best" forecast of this functional. In contrast, in some economic applications, the target functional is not known or stated explicitly, and instead the decision in which the forecast will be used is specified, which "traces out" a particular economic loss function (and in turn implies a particular statistical functional as the target). See Leitch and Tanner (1991), West, *et al.* (1993) and Skouras (2007) for examples. While distinct, the recommendation from this paper is related: in the presence of potential model misspecification or nonnested information sets, forecast producers should be told the specific loss function that will be used to evaluate their predictions. When the target functional is known, the given loss function should of course be consistent for that functional, but in the presence of model misspecification or nonnested information, merely specifying the target functional is not sufficient.

I illustrate these ideas in this paper with a study of the inflation forecasting performance of respondents to the Survey of Professional Forecasters (SPF) and the Michigan Survey of Consumers. Under squared-error loss, I find that the SPF consensus forecast and the Michigan consensus forecast are very similar in accuracy, with slight preference to the SPF, but when a Bregman loss function is used that penalizes over- or under-predictions more heavily, the ranking of these forecasts switches. I also consider comparisons of individual respondents to the SPF, and find cases where the ranking of two forecasters is very sensitive to the particular choice of Bregman loss function, and where the ranking is robust across a range of Bregman loss functions.

This paper is related to several recent papers on related topics. Elliott, *et al.* (2014) study the problem of forecasting binary variables with binary forecasts, and the evaluation and estimation

of models based on consistent loss functions. They obtain several useful, closed-form, results for this case. Merkle and Steyvers (2013) also consider forecasting binary variables, and provide an example where the ranking of forecasts is sensitive to the choice of consistent loss function. Holzmann and Eulert (2014) show in a very general framework that forecasts based on larger information sets lead to lower expected loss, and apply their results to Value-at-Risk forecasting. This paper builds on these works, and the important work of Gneiting (2011a), to show the strong conditions under which the ranking of a forecast of a given statistical functional is insensitive to the choice of loss function, even when that choice is constrained to the set of loss functions that are consistent for the given functional. Examples and illustrations designed to resemble those faced in economic forecasting applications highlight the relevance of the problem, and provide support for the key recommendation of this paper: when conducting surveys or forecast competitions, forecast producers should be told not only the statistical functional of interest, but rather the specific loss function that will be used to evaluate their predictions.

The remainder of the paper is structured as follows. Section 2 presents positive and negative results in the absence and presence of real-world complications like nonnested information sets and misspecified models, and Section 3 presents some extensions. Section 4 considers realistic simulation designs that illustrate the main ideas, and Section 5 presents an analysis of US inflation forecasts. The appendix presents proofs, and a web appendix contains additional details.

2 Comparing and constructing forecasts using consistent loss functions

2.1 Mean forecasts and Bregman loss functions

The most well-known loss function is the quadratic or squared-error loss function:

$$L\left(y, \hat{y}\right) = \left(y - \hat{y}\right)^2 \tag{1}$$

Under quadratic loss, the optimal forecast of a variable is well-known to be the (conditional) mean:

$$\hat{Y}_t^* \quad \equiv \quad \arg\min_{\hat{y} \in \mathcal{Y}} \; E\left[L\left(Y_t, \hat{y}\right) | \mathcal{F}_t\right] \tag{2}$$

$$= \quad E\left[Y_t | \mathcal{F}_t\right], \quad \text{if } L\left(y, \hat{y}\right) = \left(y - \hat{y}\right)^2 \tag{3}$$

where $\mathcal{F}_t$ is the forecaster's information set. More generally, the conditional mean is the optimal forecast under any loss function belonging to a general class of loss functions known as Bregman loss functions (see Banerjee, *et al.*, 2005 and Gneiting, 2011a). The class of Bregman loss functions is then said to be "consistent" for the (conditional) mean functional. Elements of the Bregman class of loss functions, denoted $\mathcal{L}_{Bregman}$, take the form:

$$L\left(y, \hat{y}\right) = \phi\left(y\right) - \phi\left(\hat{y}\right) - \phi'\left(\hat{y}\right)\left(y - \hat{y}\right) \tag{4}$$

where $\phi : \mathcal{Y} \to \mathbb{R}$ is any strictly convex function, and $\mathcal{Y}$ is the support of Y_t. Moreover, this class of loss functions is also *necessary* for conditional mean forecasts, in the sense that if the optimal forecast is known to be the conditional mean, then it must be that the forecast was generated by minimizing the expected loss of some Bregman loss function. Two prominent examples of Bregman loss functions are quadratic loss (equation (1)) and QLIKE loss, which is applicable for strictly positive random variables:

$$L\left(y, \hat{y}\right) = \frac{y}{\hat{y}} - \log\frac{y}{\hat{y}} - 1 \tag{5}$$

The quadratic and QLIKE loss functions are particularly special, in that they are the only two Bregman loss functions that only depend on the difference (Savage, 1971) or the ratio (Patton, 2011) of the target variable and the forecast.

To illustrate the variety of shapes that Bregman loss functions can take, two parametric families of Bregman loss for variables with support on the real line are presented below. The first was proposed in Gneiting (2011a), and is a family of homogeneous loss functions, where the "shape" parameter determines the degree of homogeneity. It is generated by using $\phi\left(x; k\right) = |x|^k$ for $k > 1$:

$$L\left(y, \hat{y}; k\right) = |y|^k - |\hat{y}|^k - k \, \text{sgn}\left(\hat{y}\right) |\hat{y}|^{k-1}\left(y - \hat{y}\right), \quad k > 1 \tag{6}$$

This family nests the squared-error loss function at $k = 2$. (The non-differentiability of ϕ can be ignored if Y_t is continuously distributed, and the absolute value components can be dropped

altogether if the target variable is strictly positive, see Patton, 2011). A second, non-homogeneous, family of Bregman loss can be obtained using $\phi(x; a) = 2a^{-2} \exp\{ax\}$ for $a \neq 0$:

$$L(y, \hat{y}; a) = \frac{2}{a^2} \left(\exp\{ay\} - \exp\{a\hat{y}\} \right) - \frac{2}{a} \exp\{a\hat{y}\} (y - \hat{y}), \quad a \neq 0 \tag{7}$$

This family nests the squared-error loss function as $a \to 0$. This loss function has some similarities to the "Linex" loss function, see Varian (1974) and Zellner (1986), in that it involves both linear and exponential terms, however a key difference is that the above family implies that the optimal forecast is the conditional mean, not a function of the conditional mean and higher-order moments.

Figure 1 illustrates the variety of shapes that Bregman loss functions can take and reveals that although all of these loss functions yield the mean as the optimum forecast, their shapes can vary widely: these loss functions can be asymmetric, with either under-predictions or over-predictions being more heavily penalized, and they can be strictly convex or have concave segments. Thus restricting attention to loss functions that generate the mean as the optimum forecast does *not* require imposing symmetry or other such assumptions on the loss function. Similarly, in the literature on economic forecasting under asymmetric loss (see Granger, 1969, Christoffersen and Diebold, 1997, and Patton and Timmermann, 2007, for example), it generally thought that asymmetric loss functions necessarily lead to optimal forecasts that differ from the conditional mean (they contain an "optimal bias" term). Figure 1 reveals that asymmetric loss functions can indeed still imply the conditional mean as the optimal forecast. (In fact, Savage (1971) shows that of the infinite number of Bregman loss functions, only one is symmetric: the quadratic loss function.)

[INSERT FIGURE 1 ABOUT HERE]

2.2 Correctly specified models and nested information sets

While forecasts are of course based on conditioning information, I will consider ranking forecasts by their unconditional average loss, a quantity that is estimable, under standard regularity conditions, given a sample of data. For notational simplicity, I assume strict stationarity of the data, but certain forms of heterogeneity can be accommodated by using results for heterogeneous processes, see White (2001) for example. I use t to denote an observation, for example a time period, however

7

the results in this paper are applicable wherever one has repeated observations, for example election forecasting across states, sales forecasting across individual stores, etc.

Firstly, consider a case where forecasters A and B are ranked by mean squared error (MSE)

$$MSE_i \equiv E\left[\left(Y_t - \hat{Y}_t^i\right)^2\right], \quad i \in \{A, B\} \tag{8}$$

and we then seek to determine whether

$$MSE_A \lesseqgtr MSE_B \Rightarrow E\left[L\left(Y_t, \hat{Y}_t^A\right)\right] \lesseqgtr E\left[L\left(Y_t, \hat{Y}_t^B\right)\right] \quad \forall L \in \mathcal{L}_{Bregman} \tag{9}$$

subject to these expectations existing. The following proposition provides conditions under which the above implication holds. (Holzmann and Eulert (2014) show in a very general framework that forecasts based on larger information sets lead to lower expected loss, including the mean case below as well as other point forecasting applications. Their method of proof is quite different, and their interpretation differs from here.)

Proposition 1 *Assume that (i) The information sets of the two forecasters are nested, so $\mathcal{F}_t^B \subseteq \mathcal{F}_t^A \; \forall t$ or $\mathcal{F}_t^A \subseteq \mathcal{F}_t^B \; \forall t$, and (ii) Forecasts A and B are optimal under some Bregman loss function. Then the ranking of these forecasts by MSE is sufficient for their ranking by any Bregman loss function.*

Proof of Proposition 1. We will show that under assumptions (i) and (ii), $MSE_B \geq MSE_A \Rightarrow \mathcal{F}_t^B \subseteq \mathcal{F}_t^A \; \forall t \Rightarrow E\left[L\left(Y_t, \hat{Y}_t^B\right)\right] \geq E\left[L\left(Y_t, \hat{Y}_t^A\right)\right] \; \forall L \in \mathcal{L}_{Bregman}$.

For the first implication: We are given that $MSE_B \geq MSE_A$, and assume that $\mathcal{F}_t^A \subseteq \mathcal{F}_t^B \; \forall t$. This means that $\min_{\hat{y}} \; E\left[(Y_t - \hat{y})^2 \,|\mathcal{F}_t^A\right] \geq \min_{\hat{y}} \; E\left[(Y_t - \hat{y})^2 \,|\mathcal{F}_t^B\right]$ *a.s.* $\forall t$, and so $E\left[\left(Y_t - \hat{Y}_t^A\right)^2 |\mathcal{F}_t^A\right] \geq E\left[\left(Y_t - \hat{Y}_t^B\right)^2 |\mathcal{F}_t^B\right]$ *a.s.* $\forall t$ by assumption (ii), and $E\left[\left(Y_t - \hat{Y}_t^A\right)^2\right] \geq E\left[\left(Y_t - \hat{Y}_t^B\right)^2\right]$ by the law of iterated expectations, which is a contradiction. Thus $MSE_B \geq MSE_A \Rightarrow \mathcal{F}_t^B \subseteq \mathcal{F}_t^A \; \forall t$.

Now consider the second implication: Let

$$Y_t = \hat{Y}_t^A + \eta_t = \hat{Y}_t^B + \eta_t + \varepsilon_t \tag{10}$$

Then

$$E\left[L\left(Y_t, \hat{Y}_t^A\right) - L\left(Y_t, \hat{Y}_t^B\right)\right] = E\left[-\phi\left(\hat{Y}_t^A\right) - \phi'\left(\hat{Y}_t^A\right)\eta_t + \phi\left(\hat{Y}_t^B\right) + \phi'\left(\hat{Y}_t^B\right)(\eta_t + \varepsilon_t)\right]$$
$$= E\left[\phi\left(\hat{Y}_t^B\right) - \phi\left(\hat{Y}_t^A\right)\right] \tag{11}$$

since $E\left[\phi'\left(\hat{Y}_t^A\right)\eta_t\right] = E\left[\phi'\left(\hat{Y}_t^A\right)E\left[\eta_t|\mathcal{F}_t^A\right]\right]$ by the law of iterated expectations and $E\left[\eta_t|\mathcal{F}_t^A\right] = 0$, and similarly for $E\left[\phi'\left(\hat{Y}_t^B\right)(\eta_t + \varepsilon_t)\right]$. Next, consider the second-order mean-value expansion:

$$\phi\left(\hat{Y}_t^A\right) = \phi\left(\hat{Y}_t^B\right) - \phi'\left(\hat{Y}_t^B\right)\varepsilon_t + \phi''\left(\ddot{Y}_t^A\right)\varepsilon_t^2 \tag{12}$$

where $\ddot{Y}_t^A = \lambda_t \hat{Y}_t^A + (1-\lambda_t)\hat{Y}_t^B$, for $\lambda_t \in [0,1]$. Thus

$$E\left[L\left(Y_t, \hat{Y}_t^A\right) - L\left(Y_t, \hat{Y}_t^B\right)\right] = E\left[\phi'\left(\hat{Y}_t^B\right)\varepsilon_t\right] - E\left[\phi''\left(\ddot{Y}_t^A\right)\varepsilon_t^2\right] \le 0 \tag{13}$$

since $E\left[\phi'\left(\hat{Y}_t^B\right)\varepsilon_t\right] = 0$ and ϕ is convex. ∎

Thus under the strong assumptions of comparing only forecasters with nested information sets, and who use only correctly specified models with no estimation error, the ranking obtained by MSE is sufficient the ranking by *any* Bregman loss function. This of course also implies that ranking forecasts by a variety of different Bregman loss functions adds no information beyond ranking by any single Bregman loss function.

2.3 Misspecified models or non-nested information sets

Next we consider deviations from the two assumptions underlying the above result. In part (a) of the following proposition we consider the case that both forecasters are able to construct fully accurate estimates of the conditional mean, but their information sets are non-nested. This is a plausible scenario in practice, if we consider a variety of experts trying to predict a complicated variable, all working to gather new and useful information to construct their forecasts. It is particularly relevant if we compare two "types" of forecasters, such as professional forecasters and consumers, as in the empirical application in Section 5, whose access to different types of data differs. In part (b) we consider the case that the forecasters may be using misspecified models, which we take here to also include correctly-specified models that are subject to estimation error. Like the case of non-nested information sets, and perhaps even more so, this is a very plausible scenario in practice.

9

Proposition 2 *Assume that (a) the information sets of the two forecasters are non-nested, so $\mathcal{F}_t^B \nsubseteq \mathcal{F}_t^A$ and $\mathcal{F}_t^A \nsubseteq \mathcal{F}_t^B$ for some t, but Forecasts A and B are optimal under some Bregman loss function, or (b) at least one of the forecasts is based on a misspecified model. Then the ranking of these forecasts is, in general, sensitive to the choice of Bregman loss function.*

The web appendix contains a simple example supporting the above proposition, based on two-point and three-point random variables, and Merkle and Styvers (2013) present an example for forecasts of binary variables. An example more closely related to economic applications is presented in Section 4 below. In all cases, the key insight is that the relative weight given to large and small, and positive and negative, forecast errors by different Bregman loss functions induces different rankings of the competing forecasts, when they are based on nonnested information sets or on misspecified models.

It should be noted that it might be possible to partially relax assumptions (i) and (ii) in Proposition 1, or to place other restrictions on the problem, and retain the robustness of the ranking of forecasts to the choice of Bregman loss function. For example, if the form of the model misspecification was known, or if the target variable has a particularly simple structure (e.g., a binary random variable). I do not pursue such special cases here.

The following corollary generalizes Propositions 1 and 2 to evaluating many forecasters.

Corollary 1 *Consider evaluating $N \geq 2$ forecasters.*

(a) Assume (i) there exists an ordering of the forecasters such that $\mathcal{F}_t^{(1)} \subseteq \mathcal{F}_t^{(2)} \subseteq \cdots \subseteq \mathcal{F}_t^{(N)} \; \forall \; t$, and (ii) all forecasts are optimal under some Bregman loss function. Then the ranking of these forecasts by MSE is sufficient for their ranking by any Bregman loss function.

(b) Assume (i) there exists a forecaster i^* such that $\bigcup_{i \neq i^*} \mathcal{F}_t^{(i)} \subseteq \mathcal{F}_t^{(i^*)} \; \forall \; t$, and (ii) forecast i^* is optimal under some Bregman loss function. Then forecaster i^* will have the lowest average loss using any Bregman loss function, including MSE. The ranking of the other (non i^*) forecasters will, in general, be sensitive to the choice of loss function.

10

2.4 Optimal approximations

We now consider the problem of calibrating a parametric forecasting model to generate the best (in some sense) prediction. First, we show that if the model is correctly specified, then minimizing the expected loss under any Bregman loss function will yield a consistent estimator of the model's parameters. However if the model is misspecified, then different Bregman estimators will yield different estimators, in the sense that they converge to different probability limits. Elliott, *et al.* (2014) provide several useful related results on this problem when both the target variable and the forecast are binary. They show that even in their relatively tractable case, the presence of model misspecification generally leads to sensitivity of estimated parameters to the choice of (consistent) loss function.

Assumption (i) below simply states that the conditional mean has a parametric form, with true parameter θ_0. Assumption (ii) is required for identification, imposing that the conditional mean is sensitive to changes in the parameter θ.

Proposition 3 *Assume that (i)* $E[Y_t|\mathcal{F}_t] = m(Z_t;\theta_0)$, *for some* $\theta_0 \in \Theta \subseteq \mathbb{R}^p$, $p < \infty$, *and (ii)* $\partial m(Z_t;\theta)/\partial\theta \neq 0$ *a.s.* $\forall \theta \in \Theta$. *Define*

$$\hat{\theta}_{\phi}^* \equiv \arg\min_{\theta \in \Theta} \ E\left[L\left(Y_t, m\left(Z_t;\theta\right);\phi\right)\right] \tag{14}$$

where L *is a Bregman loss function characterized by the convex function* ϕ. *Then* $\hat{\theta}_{\phi}^* = \theta_0 \ \forall \ \phi$.

Next we consider an example where the model is misspecified,and show that different Bregman estimators can yield quite different approximations. Consider the following simple DGP:

$$Y \ = \ X^2 + \varepsilon \tag{15}$$

$$[X,\varepsilon] \ \sim \ iid \ N\left([\mu,0], diag\left\{\left[\sigma^2,1\right]\right\}\right)$$

But the forecasters use only a linear model:

$$Y = \alpha + \beta X + e \tag{16}$$

For this illustration, consider forecasters using the "Exponential Bregman" loss function defined in equation (7). Using results for functions of Normal random variables (see the appendix for details)

we can analytically derive the optimal linear model parameters $[\alpha, \beta]$ as a function of a, the loss function parameter, subject to the condition that $a \neq \left(2\sigma^2\right)^{-1}$:

$$
\begin{aligned}
\hat{\alpha}_a^* &= \sigma^2 - \frac{\mu^2}{(1 - 2a\sigma^2)^2} \\
\hat{\beta}_a^* &= \frac{2\mu}{1 - 2a\sigma^2}
\end{aligned}
\tag{17}
$$

This simple example reveals some important features of the problem of loss function-based parameter estimation in the presence of model misspecification. Firstly, the loss function shape parameter does not always affect the optimal model parameters. In this example, if $X \sim N\left(0, \sigma^2\right)$, then $\left(\hat{\alpha}_a^*, \hat{\beta}_a^*\right) = \left(\sigma^2, 0\right)$ for all values of the loss function parameter a. Second, identification issues can arise even when the model appears to be *prima facie* well identified. In this example, the estimation problem is not identified at $a = \left(2\sigma^2\right)^{-1}$. Issues of identification when estimating under the "relevant" loss function have been previously documented, see Weiss (1996) and Skouras (2007).

Finally, we note that when $\mu \neq 0$, the optimal model parameters will vary with the loss function parameter, and thus the choice of loss function to use in estimation will affect the approximation yielded by the misspecified model. Figure 2 illustrates this point, presenting the optimal linear approximations for three choices of exponential Bregman parameter, when $\mu = \sigma^2 = 1$. The optimal parameters are presented in Table 1. The approximation yielded by OLS regression is obtained when $a = 0$, and there we see the intercept is zero and the slope coefficient is two. If we consider a loss function that places greater weight on errors that occur for low values of the forecast $(a = -0.5)$ the line flattens and the upper panel of Figure 2 shows that this yields a better fit for the left side of the distribution of the predictor variable. The opposite occurs if we consider a loss function that places greater weight on errors that occur for high values of the forecast $(a = 0.25)$. The lower panel of Figure 2 presents a simple nonparametric estimate of the distance between the realization and the forecast as a function of the predictor variable. For OLS $(a = 0)$, the distance is lowest for X approximately in the interval $(0, 2)$, which covers most of the data, since $X \sim N(1, 1)$ in this example. For $a = -0.5$ the distance is lowest for X approximately in the interval $(-1, 1.5)$, while for $a = 0.25$ the distance is lowest for X approximately in the interval $(1, 3)$.

[INSERT FIGURE TABLE 1 AND 2 ABOUT HERE]

12

The above results motivate declaring the specific loss function that will be used to evaluate forecasts, so that survey respondents can optimize their (potentially misspecified) models taking the relevant loss function into account. However, it is important to note that it is not always the case that optimizing the model using the relevant loss function is optimal in finite samples: there is a trade-off between bias in the estimated parameters (computed relative to the probability limits of the parameter estimates obtained using the relevant loss function) and variance (parameter estimation error). It is possible that an efficient (low variance) but biased estimation method could out-perform a less efficient but unbiased estimation method in finite samples. See Elliott, *et al.* (2014) for discussion and examples of this for the binary prediction problem. One interpretation of the results in this section is that if all estimators converge to the same quantity then there is no bias-variance trade-off, and one need only look for the most efficient estimator, but a trade-off exists when the models are misspecified and the estimators generally converge to different quantities.

3 Extensions

This section considers some extensions of the main results in the previous section. We first consider the analogs of the above results for quantile forecasts and density forecasts, and then an additional case for mean forecasting motivated by a symmetry assumption often made in empirical work.

3.1 Quantile forecasts

This section presents results for quantile forecasts that correspond to those above for mean forecasts. The corresponding result for the necessity and sufficiency of Bregman loss for mean forecasts is presented in Saerens (2000), see also Komunjer (2005), Gneiting (2011b) and Thomson (1979): the loss function that is necessary and sufficient for quantile forecasts is called a "generalized piecewise linear" (GPL) loss function, denoted $\mathcal{L}_{GPL}^{\alpha}$:

$$L(y, \hat{y}; \alpha) = (\mathbf{1}\{y \leq \hat{y}\} - \alpha)(g(\hat{y}) - g(y)) \tag{18}$$

where g is a nondecreasing function, and $\alpha \in (0, 1)$ indicates the quantile of interest. A prominent example of a GPL loss function is the "Lin-Lin" (or "tick") loss function, which is obtained when

g is the identity function:

$$L(y, \hat{y}; \alpha) = (\mathbf{1}\{y \leq \hat{y}\} - \alpha)(\hat{y} - y) \tag{19}$$

and which nests absolute error (up to scale) when $\alpha = 1/2$. However, there are clearly an infinite number of loss functions that are consistent for the α quantile. The following is a homogeneous parametric GPL family of loss functions (for variables with support on the real line) related to that proposed by Gneiting (2011b):

$$L(y, \hat{y}; \alpha, b) = (\mathbf{1}\{y \leq \hat{y}\} - \alpha)\left(\operatorname{sgn}(\hat{y})|\hat{y}|^b - \operatorname{sgn}(y)|y|^b\right)/b, \quad b > 0 \tag{20}$$

Figure 3 below presents some elements of this family of loss functions for $\alpha = 0.5$ and $\alpha = 0.25$, and reveals that although the optimal forecast is always the same under all of these loss functions (with the same α), their individual shapes can vary substantially.

When the loss function belongs to the GPL family, the optimal forecast satisfies

$$\alpha = E\left[\mathbf{1}\left\{Y_t \leq \hat{Y}_t^*\right\}|\mathcal{F}_t\right] \equiv F_t\left(\hat{Y}_t^*\right) \tag{21}$$

where $Y_t|\mathcal{F}_t \sim F_t$, and if the conditional distribution function is strictly increasing, then $\hat{Y}_t^* = F_t^{-1}(\alpha|\mathcal{F}_t)$. Now we seek to determine whether the ranking of two forecasts by Lin-Lin loss is sufficient for their ranking by any GPL loss function (with the same α parameter). That is, whether

$$LinLin_A^\alpha \lessgtr LinLin_B^\alpha \Rightarrow E\left[L\left(Y_t, \hat{Y}_t^A\right)\right] \lessgtr E\left[L\left(Y_t, \hat{Y}_t^B\right)\right] \quad \forall L \in \mathcal{L}_{GPL}^\alpha \tag{22}$$

subject to these expectations existing. Under the analogous conditions to those for the conditional mean, a sufficiency result obtains. See Holzmann and Eulert (2014) for a related result.

Proposition 4 *Assume that (i) The information sets of the two forecasters are nested, so $\mathcal{F}_t^B \subseteq \mathcal{F}_t^A \; \forall t$ or $\mathcal{F}_t^A \subseteq \mathcal{F}_t^B \; \forall t$, and (ii) Forecasts A and B are optimal under some $\mathcal{L}_{GPL}^\alpha$ loss function. Then the ranking of these forecasts by expected Lin-Lin loss is sufficient for their ranking by any $\mathcal{L}_{GPL}^\alpha$ loss function.*

Next again consider deviations from the two assumptions underlying the above result, namely allowing the information sets of the two forecasters to be nonnested, or allowing for model misspecification. As in the conditional mean case, either of these complications is enough to induce

14

sensitivity to the choice of loss function of the ranking of two quantile forecasts. A simple example supporting this proposition is presented in the web appendix, and a more realistic example is presented in Section 4 below.

Proposition 5 *Assume that (a) The information sets of the two forecasters are non-nested, so* $\mathcal{F}_t^B \nsubseteq \mathcal{F}_t^A$ *and* $\mathcal{F}_t^A \nsubseteq \mathcal{F}_t^B$ *for some t, but Forecasts A and B are optimal under some GPL loss function, or (b) one or both of the α-quantile forecasts are based on misspecified models. Then the ranking of these forecasts is, in general, sensitive to the choice of GPL loss function.*

3.2   Density forecasts

We now consider results corresponding to the mean and quantile cases above for density or distribution forecasts. In this case the central idea is the use of a proper scoring rule. A "scoring rule," see Gneiting and Ranjan (2011) for example, is a loss function mapping the density or distribution forecast and the realization to a measure of gain/loss. (In density forecasting this is often taken as a gain, but for comparability with the above two sections I will treat it here as a loss, so that lower values are preferred.) A "proper" scoring rule is any scoring rule such that it is minimized in expectation when the distribution forecast is equal to the true distribution. That is, L is proper if

$$E_F\left[L\left(F,Y\right)\right] \equiv \int L\left(F,y\right)dF\left(y\right) \leq E_F\left[L\left(\tilde{F},Y\right)\right] \tag{23}$$

for all distribution functions F, $\tilde{F} \in \mathcal{P}$, where $\mathcal{P}$ is the class of probability measures being considered. (I will use distributions rather than densities for the main results here, so that they are applicable more generally.) Gneiting and Raftery (2007) show that if L is a proper scoring rule then it must be of the form:

$$L\left(F,y\right) = \Psi\left(F\right) + \Psi^*\left(F,y\right) - \int \Psi^*\left(F,y\right)dF\left(y\right) \tag{24}$$

where Ψ is a convex, real-valued function, and Ψ^* is a subtangent of Ψ at the point $F \in \mathcal{P}$. I denote the set of proper scoring rules satisfying equation (24) as $\mathcal{L}_{\mathrm{Proper}}$. As an example of a proper scoring rule, consider the "weighted continuous ranked probability score" from Gneiting and Ranjan (2011):

$$wCRPS\left(F,y;\omega\right) = \int_{-\infty}^{\infty} \omega\left(z\right)\left(F\left(z\right) - \mathbf{1}\left\{y \leq z\right\}\right)^2 dz \tag{25}$$

where ω is a nonnegative weight function on $\mathbb{R}$. If ω is constant then the above reduces to the (unweighted) CRPS loss function.

Now we seek to determine whether the ranking of two forecasts by two distribution forecasts by any single proper scoring rule is consistent for their ranking by any proper scoring rule.

$$E\left[L_i\left(F_t^A, Y_t\right)\right] \lesseqgtr E\left[L_i\left(F_t^B, Y_t\right)\right] \Rightarrow E\left[L_j\left(F_t^A, Y_t\right)\right] \lesseqgtr E\left[L_j\left(F_t^B, Y_t\right)\right] \ \forall L_j \in \mathcal{L}_{\text{Proper}} \qquad (26)$$

Under the analogous conditions to those for the conditional mean and conditional quantile, a sufficiency result obtains.

Proposition 6 *Assume that (i) the information sets of the two forecasters are nested, so $\mathcal{F}_t^B \subseteq \mathcal{F}_t^A \ \forall t$ or $\mathcal{F}_t^A \subseteq \mathcal{F}_t^B \ \forall t$, and (ii) F_t^A and F_t^B are the conditional distributions of $Y_t|\mathcal{F}_t^A$ and $Y_t|\mathcal{F}_t^B$ respectively. Then the ranking of these forecasts by any given proper scoring rule is sufficient for their ranking by any other proper scoring rule.*

Now consider again deviations from the two assumptions underlying the above result, where we allow the information sets of the two forecasters to be nonnested, or for model misspecification. As in the conditional mean and conditional quantile cases, either of these situations is enough to induce sensitivity to the choice of loss function of the ranking of two distribution forecasts. A simple example supporting this proposition is presented in the web appendix, and a more realistic example is given in Section 4 below.

Proposition 7 *Assume that (a) the information sets of the two forecasters are non-nested, so $\mathcal{F}_t^B \nsubseteq \mathcal{F}_t^A$ and $\mathcal{F}_t^A \nsubseteq \mathcal{F}_t^B$ for some t, but F_t^A and F_t^B are the conditional distributions of $Y_t|\mathcal{F}_t^A$ and $Y_t|\mathcal{F}_t^B$ respectively, or (b) one or both of the distribution forecasts are based on misspecified models. Then the ranking of these forecasts is, in general, sensitive to the choice of proper scoring rule.*

3.3 Mean forecasts of symmetric random variables

In many economic applications the target variable is assumed to be symmetrically distributed. In the following proposition we show if this assumption is made, then the class of loss functions that leads to the forecasters revealing their conditional mean is larger than in the general case in Section

2.1. In the first part of the following proposition we establish the relevant class of loss functions in this case. The second and third parts present results on ranking forecasters when the assumptions of correctly-specified models and nested information sets hold, or fail to hold.

Proposition 8 *Assume that (i) forecaster j optimizes his/her forecast with respect to a symmetric continuous distribution $F_t^{(j)}$, for all j. Then, (a) any convex combination of a Bregman and a $GPL^{1/2}$ loss function, $\mathcal{L}_{Breg \times GPL} \equiv \lambda \mathcal{L}_{Bregman} + (1 - \lambda) \mathcal{L}_{GPL}^{1/2}$, $\lambda \in [0, 1]$, yields the mean of $F_t^{(j)}$ as the optimal forecast.*

(b) Assume that (ii) The information sets of the two forecasters are nested, so $\mathcal{F}_t^B \subseteq \mathcal{F}_t^A \ \forall t$ or $\mathcal{F}_t^A \subseteq \mathcal{F}_t^B \ \forall t$, and (iii) Forecasts A and B are optimal under some loss function in $\mathcal{L}_{Breg \times GPL}$. Then the ranking of these forecasts by MSE or MAE is sufficient for their ranking by any loss function in $\mathcal{L}_{Breg \times GPL}$.

(c) Assume that (ii') the information sets of the two forecasters are non-nested, so $\mathcal{F}_t^B \nsubseteq \mathcal{F}_t^A$ and $\mathcal{F}_t^A \nsubseteq \mathcal{F}_t^B$ for some t, but Forecasts A and B are optimal under some loss function in $\mathcal{L}_{Breg \times GPL}$, or (iii') at least one of the forecasts is based on a misspecified model. Then the ranking of these forecasts is, in general, sensitive to the choice of loss function in $\mathcal{L}_{Breg \times GPL}$.

Thus if forecasters are known to be using a symmetric model for the target variable, regardless of whether that assumption is correct, then the class of loss functions that is consistent for the mean is now *even larger* than the Bregman class: it is the convex combination of the Bregman and the GPL$^{1/2}$ class of loss functions. This suggests that it is even more important to declare which specific loss function will be used to rank the forecasts, as the set of loss functions that might be being used by survey respondents is even larger than in either the mean (Bregman) or median (GPL$^{1/2}$) forecasting cases.

4 Simulation-based results for realistic scenarios

In this section I present four scenarios to provide a more realistic description of the real-world complications involved with forecast construction, and show that these complications lead to sensitivity in the ranking of competing forecasts to the choice of consistent or proper loss functions.

For the first example, consider a point forecast based on a Bregman loss function, and so the target functional is the conditional mean. Assume that the data generating process is a stationary AR(5), with a strong degree of persistence:

$$Y_t = Y_{t-1} - 0.02Y_{t-2} - 0.02Y_{t-3} - 0.01Y_{t-4} - 0.01Y_{t-5} + \varepsilon_t, \ \ \varepsilon_t \sim iid \ N(0,1) \qquad (27)$$

As forecasts, consider the comparison of a misspecified (but parsimonious) model with a correctly-specified model that is subject to estimation error. The first forecast is based on a random walk assumption:

$$\hat{Y}_t^A = Y_{t-1} \qquad (28)$$

and the second forecast is based on a (correctly-specified) AR(5) model with parameters estimated using OLS on a rolling window of 100 observations:

$$\hat{Y}_t^B = \hat{\phi}_{0,t} + \hat{\phi}_{1,t}Y_{t-1} + \hat{\phi}_{2,t}Y_{t-2} + \hat{\phi}_{3,t}Y_{t-3} + \hat{\phi}_{4,t}Y_{t-4} + \hat{\phi}_{5,t}Y_{t-5} \qquad (29)$$

where $\hat{\phi}_{j,t}$ is the estimate of ϕ_j based on data from $t - 100$ to $t - 1$. I simulate this design for 10,000 observations, and report the differences in average losses for a variety of homogeneous and exponential Bregman loss functions in Figure 4. From this figure we see that the ranking of these two forecasts is indeed sensitive to the choice of Bregman loss function. Under squared-error loss (corresponding to parameters 2 and 0 respectively for the homogeneous and exponential Bregman loss functions) the average loss difference is negative, indicating that the AR(5) model has larger average loss than the random walk model, and thus the use of a parsimonious but misspecified model is preferred to the use of a correctly specified model that is subject to estimation error. However, the ranking is reversed for homogeneous Bregman loss functions with parameter above about 3.5, and for exponential Bregman loss functions with parameter greater than about 0.5 in absolute value.

[INSERT FIGURE 4 ABOUT HERE]

For our second example consider quantile forecasts for a heteroskedastic time series process. Consider a target variable governed by an AR-GARCH model, with parameters representative of

18

those found for daily stock returns:

$$Y_t = \mu_t + \sigma_t \varepsilon_t, \ \ \varepsilon_t \sim N(0,1)$$

$$\text{where} \ \ \mu_t = 0.03 + 0.05 Y_{t-1} \quad (30)$$

$$\sigma_t^2 = 0.05 + 0.9\sigma_{t-1}^2 + 0.05\sigma_{t-1}^2 \varepsilon_{t-1}^2$$

I compare two forecasts based on non-nested information sets. The first forecast exploits knowledge of the conditional mean, but assumes a constant conditional variance, while the second is the reverse:

$$\hat{Y}_t^A = \mu_t + \bar{\sigma}\Phi^{-1}(\alpha) \quad (31)$$

$$\hat{Y}_t^B = \bar{\mu} + \sigma_t\Phi^{-1}(\alpha)$$

where $\bar{\mu} = E[Y_t]$ and $\bar{\sigma}^2 = V[Y_t]$. I consider these forecasts for two quantiles, a tail quantile $(\alpha = 0.05)$ and a quantile somewhere between the tail and the center of the distribution $(\alpha = 0.25)$. I compare these forecasts using the homogeneous GPL loss function in equation (20), and report the results based on a simulation of 10,000 observations.

In the right panel of Figure 5, where $\alpha = 0.05$, we see that the forecaster who has access to volatility information (Forecaster B) has lower average loss, across all values of the loss function parameter, than the forecaster who has access only to mean information. This is consistent with previous empirical research on the importance of volatility on estimates of tails. However, when looking at a quantile somewhere between the tails and the center, $\alpha = 0.25$, we see that the ranking of these forecasts switches: for loss function parameter values less than about one, the forecaster with access to mean information has lower average loss, while for loss function parameter values above one we see the opposite.

[INSERT FIGURE 5 ABOUT HERE]

In a third example, consider the problem of forecasting the distribution of the target variable. I use a GARCH(1,1) specification (Bollerslev, 1986) for the conditional variance, and a left-skewed

19

t distribution (Hansen, 1994) for the standardized residuals:

$$
\begin{aligned}
Y_t &= \sigma_t \varepsilon_t \\
\sigma_t^2 &= 0.05 + 0.9\sigma_{t-1}^2 + 0.05\sigma_{t-1}^2 \varepsilon_{t-1}^2 \\
\varepsilon_t &\sim \ iid \ Skew \ t\,(0, 1, 6, -0.25)
\end{aligned}
\tag{32}
$$

I take the first distribution forecast to be based on the Normal distribution, with mean zero and variance estimated using the past 100 observations:

$$
\hat{F}_{A,t}(x) = \Phi\left(\frac{x}{\hat{\sigma}_t}\right), \quad \text{where} \ \ \hat{\sigma}_t^2 = \frac{1}{100}\sum_{j=1}^{100} Y_{t-j}^2
\tag{33}
$$

This is a parsimonious specification, but it imposes an incorrect model for the predictive distribution. The second forecast is based on the empirical distribution function (EDF) of the data over the past 100 observations:

$$
\hat{F}_{B,t}(x) = \frac{1}{100}\sum_{j=1}^{100} \mathbf{1}\left\{Y_{t-j} \leq x\right\}
\tag{34}
$$

This nonparametric specification is more flexible than the first, but will inevitably contain more estimation error. I consider the weighted CRPS scoring rule from equation (25) where the weights are based on the standard Normal CDF:

$$
\omega(z; \lambda) \equiv \lambda\Phi(z) + (1 - \lambda)(1 - \Phi(z)), \ \ \lambda \in [0, 1]
\tag{35}
$$

When $\lambda = 0$, the weight function is based on $1 - \Phi$, and thus places more weight on the left tail than the right tail. When $\lambda = 0.5$ the weighting scheme is flat and weights both tails equally. When $\lambda = 1$ the weight function places more weight on the right tail than the left tail.

This design is simulated for 10,000 observations, and the differences in average losses across weighting schemes (λ) are shown in Figure 6. We see that the ranking of these two distribution forecasts is sensitive to the choice of (proper) scoring rule: for weights below about 0.25 (i.e., those with a focus on the left tail), we find the EDF is preferred to the Normal distribution, while for weights above 0.25, including the equal-weighted case at 0.5, the Normal distribution is preferred to the EDF. Thus, the additional estimation error in the EDF generally leads to it being beaten by the parsimonious, misspecified, Normal distribution, *unless* the scoring rule places high weight on the left tail, which is long given the left-skew in the true distribution.

[INSERT FIGURE 6 ABOUT HERE]

Finally, related to the optimal approximation problem described in Section 2.4, consider the problem of approximating the true process for the conditional variance of an asset return with some misspecified model. We take the DGP to be a GARCH(1,1):

$$
\begin{aligned}
y_t &= \sigma_t \varepsilon_t, \ \ \varepsilon_t \sim \text{iid } F_\varepsilon (0, 1; \nu) \qquad\qquad (36) \\
\sigma_t^2 &= \bar{\sigma}^2 (1 - \alpha - \beta) + \beta \sigma_{t-1}^2 + \alpha y_{t-1}^2
\end{aligned}
$$

We use a scaled and re-centered χ_ν^2 distribution for F_ε, which generates (positive) skewness in the standardized residuals. (This is done so that optimization under the "QLIKE" loss function does not correspond to maximum likelihood, which has optimality properties that are not common for loss function-based estimators.) We consider approximating this variable using an ARCH(1) model:

$$
\tilde{\sigma}_t^2 = \gamma_0 + \gamma_1 y_{t-1}^2 \qquad\qquad (37)
$$

We consider two methods for estimating the coefficients of the approximating model: the first is Gaussian quasi-maximum likelihood, which corresponds to minimizing the expected loss of a homogeneous Bregman loss function with shape parameter $k = 0$. The second is using standard OLS, which corresponds to minimizing the expected loss of a homogeneous Bregman loss function with shape parameter $k = 2$. The parameters of the approximating model are estimated using a sample of T observations, and the loss from the resulting forecast is computed in an out-of-sample period containing P observations. In the simulation results below we set $T \in \{100, 500, 1000\}$, $P = 100$, and $(\bar{\sigma}^2, \beta, \alpha, \nu) = (1, 0.8, 0.1, 3)$. We repeat this simulation 10,000 times to obtain average out-of-sample losses. We also present the results for the infeasible case that $T \rightarrow \infty$ (obtained by using a sample of size 1,000,000) to see the results when estimation error is removed, highlighting the bias-variance trade-off that takes place in the presence of estimation error. (The limiting parameters for this case are presented in the bottom two rows of the table. They are the same regardless of the evaluation loss function.)

The table below reveals that for all sample sizes, including the limit, average out-of-sample loss is smaller when the parameters of the approximating model are estimated using the same loss

21

function as the one used for evaluation. This is consistent with the theory in the previous section, and with the binary prediction problem considered in Elliott, *et al.* (2014), but need not always be the case, in particular for smaller sample sizes. The key conclusion is that it is indeed possible, thus highlighting the potential importance of matching the loss functions used for estimation and evaluation when estimating a misspecified model.

[INSERT TABLE 2 ABOUT HERE]

5   Empirical illustration: Evaluating professional forecasters

In this section I illustrate the above ideas using survey forecasts of U.S. inflation. Inflation forecasts are central to many important economic decisions, perhaps most notably those of the Federal Open Markets Committee in their setting of the Federal Funds rate, but also pension funds, insurance companies, and asset markets more broadly. Inflation is also notoriously hard to predict, with many methods failing to beat a simple random walk model, see Faust and Wright (2013) for a recent comprehensive survey.

Firstly, I consider a comparison of the consensus forecast (defined as the cross-respondent median) of CPI inflation from the Survey of Professional Forecasters (available from `http://goo.gl/L4A897`), and from the Thomson Reuters/University of Michigan Survey of Consumers (available from `http://goo.gl/s8dCEz`). The SPF gathers forecasts quarterly for a range of horizons from one quarter to ten years, whereas the Michigan survey gathers forecasts monthly, but only for one- and five-year horizons. For this illustration I examine only the one-year forecast. The sample period is 1982Q3 to 2014Q1, a total of 127 observations. As the "actual" series I use the 2014Q2 vintage of the "real time" CPI data (available at `http://goo.gl/AH6gAO`). A plot of the forecasts and realized inflation series is presented in Figure 7, and summary statistics are presented in Table 3.

[INSERT FIGURE 7 AND TABLE 3 ABOUT HERE]

I also consider a comparison of individual respondents to the Survey of Professional Forecasters. These respondents are identified in the database only by a numerical identifier, and I select Forecasters 20, 506 and 528, as they all have relatively long histories of responses. For the individual comparisons I focus on the one-quarter-ahead forecast, as these have the most non-empty cells.

Given the difficulty in capturing the dynamics of inflation, it is reasonable to expect that all forecasters are subject to model misspecification. Moreover, these forecasts are quite possibly based on nonnested information sets, particularly in the comparison of professional forecasters with the Michigan survey of consumers. Thus the practical issues highlighted in Section 2 are relevant here.

Figure 8 presents the results of comparisons of these forecasts, for a range of Bregman loss functions. In the left panel I consider homogeneous Bregman loss functions (equation 6) with parameter ranging from 1.1 to 4 (nesting squared-error loss at 2) and in the right panel I consider exponential Bregman loss functions (equation 7) with parameter ranging from -1 to 1 (nesting squared-error loss at 0). In the top panel we see that the sign of the difference in average losses varies with the parameter of the loss function: the SPF forecast had (slightly) lower average loss for values of the Bregman parameter less than 2 and 0 in the homogeneous and exponential cases respectively, while the reverse holds true for parameters above these values. (The difference in average loss is very near zero for the squared-error loss case.) This indicates that the ranking of professional vs. consumer forecasts of inflation depends on whether over-predictions are more or less costly than under-predictions, see Figure 1.

In the middle panel I compare SPF forecaster 20 to forecaster 506, and we again see strong sensitivity to the choice of loss function: for loss functions that penalize under-prediction more than over-prediction (homogeneous Bregman with parameter less than two, and exponential Bregman with parameter less than zero) forecaster 20 is preferred, while when the loss functions penalize over-prediction more than under-prediction the ranking is reversed. In the lower panel we see an example of a robust ranking: Forecaster 506 has larger average loss than Forecaster 528 for all homogeneous and exponential Bregman loss functions considered; in no case does the ranking reverse.

[INSERT FIGURE 8 ABOUT HERE]

23

6 Conclusion

A key recommendation from Gneiting's (2011a) wide-ranging and important article is: *"If point forecasts are to be issued and evaluated, it is essential that either the scoring function be specified ex ante, or an elicitable target functional be named, such as the mean or a quantile of the predictive distribution, and scoring functions be used that are consistent for the target functional."* This paper shows that in the presence of realistic complexities such as nonnested forecaster information sets, misspecified predictive models, and predictive models subject to estimation error, only the first part of this recommendation stands; declaring the target functional is not generally sufficient to elicit a forecaster's best (according to a given, consistent, loss function) forecast. In light of this paper, best practice for point forecasting is to declare the specific loss function that will be used to evaluate forecasts, and to make that loss function consistent for the target functional of interest to the forecast consumer. Reacting to this, forecasters may then wish to estimate their predictive models, if a model is being used, based on the loss function that will evaluate their forecast. This will ensure that the estimated parameter converges to the parameter that minimizes expected loss under that loss function (the "pseudo-true" parameter), though a trade-off may exist between the variance of an estimator and the distance between its probability limit and the pseudo-true parameter. This is related to work on estimation under the "relevant cost function," see Weiss (1996), Christoffersen and Jacobs (2004), Skouras (2007) and Elliott, *et al.* (2014) for applications in economics and finance.

Appendix

Proof of Corollary 1. (a) The proof follows by noting that the ranking of any pair (i, j) of forecasters satisfies the conditions of Proposition 1, and by ranking all possible pairs we obtain a complete ranking of all N forecasters.

(b) Consider ranking (i, i^*). This proof requires a slight generalization of Proposition 1, to reflect the fact that only the forecaster with the larger information set (i^*, in this case) is required to issue an optimal forecast. Under assumptions (b)(i) and (b)(ii), we will show $MSE_i \geq MSE_{i^*} \Rightarrow \mathcal{F}_t^i \subseteq \mathcal{F}_t^{i^*} \; \forall t \Rightarrow E\left[L\left(Y_t, \hat{Y}_t^i\right)\right] \geq E\left[L\left(Y_t, \hat{Y}_t^{i^*}\right)\right] \; \forall L \in \mathcal{L}_{Bregman}$.

For the first implication: We are given that $MSE_i \geq MSE_{i^*}$, and assume that $\mathcal{F}_t^{i^*} \subseteq \mathcal{F}_t^i \; \forall t$. Under assumption (b)(ii) this means that forecaster i is using an optimal forecast but forecaster i^* may not be. We then have $E\left[\left(Y_t - \hat{Y}_t^{i^*}\right)^2 |\mathcal{F}_t^{i^*}\right] \geq \min_{\hat{y}} \; E\left[(Y_t - \hat{y})^2 |\mathcal{F}_t^{i^*}\right] \geq E\left[\left(Y_t - \hat{Y}_t^i\right)^2 |\mathcal{F}_t^i\right]$ $a.s. \; \forall t$, and $E\left[\left(Y_t - \hat{Y}_t^{i^*}\right)^2\right] \geq E\left[\left(Y_t - \hat{Y}_t^i\right)_t^2\right]$ by the law of iterated expectations (LIE), which is a contradiction. Thus $MSE_i \geq MSE_{i^*} \Rightarrow \mathcal{F}_t^i \subseteq \mathcal{F}_t^{i^*} \; \forall t$.

The second implication: Let

$$\bar{L}^j \equiv E\left[L\left(Y_t, \hat{Y}_t^j; \phi_j\right)\right], \; j \in \{i, i^*\}$$

where $L\left(\cdot, \cdot; \phi_j\right)$ is a Bregman loss function defined by ϕ_j, a convex function. Under assumptions (i) and (ii) we know that $\hat{Y}_t^{i^*}$ is the solution to $\min_{\hat{y}} \; E\left[L^{i^*}\left(Y_t, \hat{y}; \phi_{i^*}\right) |\mathcal{F}_t^{i^*}\right]$ where $L^{i^*} \in \mathcal{L}_{Bregman}$, ϕ_{i^*} is a convex function. Thus $\hat{Y}_t^{i^*} = E\left[Y_t |\mathcal{F}_t^{i^*}\right]$ for all possible distributions of Y_t, and from Banerjee *et al.* (2005) for example, we know that this implies that $\hat{Y}_t^{i^*}$ moreover satisfies:

$$\hat{Y}_t^{i^*} = \arg\min_{\hat{y}} \; E\left[\phi\left(Y_t\right) - \phi\left(\hat{y}\right) - \phi'\left(\hat{y}\right)\left(Y_t - \hat{y}\right) |\mathcal{F}_t^{i^*}\right]$$

for any convex function ϕ. Given that $\mathcal{F}_t^i \subseteq \mathcal{F}_t^{i^*} \; \forall t$, and acknowledging the possible suboptimality of forecast i, we then have $E\left[L\left(Y_t, \hat{Y}_t^i; \phi\right) |\mathcal{F}_t^i\right] \geq \min_{\hat{y}} \; E\left[L\left(Y_t, \hat{y}; \phi\right) |\mathcal{F}_t^i\right] \geq E\left[L\left(Y_t, \hat{Y}_t^{i^*}; \phi\right) |\mathcal{F}_t^{i^*}\right]$ $a.s. \; \forall t$ for any convex function ϕ, and by the LIE we obtain the second implication. The ranking of (i, j) for $i^* \notin \{i, j\}$ involves comparing forecasters with potentially nonnested information sets and potentially misspecified models, and so thus the results of Proposition 2 apply. ∎

Proof of Proposition 3. The first derivative of interest is

$$
\begin{aligned}
\frac{\partial}{\partial \theta} E\left[L\left(Y_t, m\left(Z_t; \theta\right); \phi\right)\right] &= E\left[\frac{\partial}{\partial \hat{y}} L\left(Y_t, \hat{y}; \phi\right)\Big|_{\hat{y}=m(Z_t; \theta)} \cdot \frac{\partial m\left(Z_t; \theta\right)}{\partial \theta}\right] \qquad (38) \\
&= E\left[\phi''\left(m\left(Z_t; \theta\right)\right)\left(Y_t - m\left(Z_t; \theta\right)\right)\frac{\partial m\left(Z_t; \theta\right)}{\partial \theta}\right]
\end{aligned}
$$

The first-order condition for the optimization is

$$
\begin{aligned}
0 &= \frac{\partial}{\partial \theta} E\left[L\left(Y_t, m\left(Z_t; \theta\right); \phi\right)\right]\Big|_{\theta=\hat{\theta}_\phi^*} \\
&= E\left[\phi''\left(m\left(Z_t; \hat{\theta}_\phi^*\right)\right)\left(Y_t - m\left(Z_t; \hat{\theta}_\phi^*\right)\right)\frac{\partial m\left(Z_t; \hat{\theta}_\phi^*\right)}{\partial \theta}\right] \qquad (39) \\
&= E\left[\phi''\left(m\left(Z_t; \hat{\theta}_\phi^*\right)\right)\left(E\left[Y_t | \mathcal{F}_t\right] - m\left(Z_t; \hat{\theta}_\phi^*\right)\right)\frac{\partial m\left(Z_t; \hat{\theta}_\phi^*\right)}{\partial \theta}\right], \quad \text{by the LIE}
\end{aligned}
$$

and note that this equality holds when $\hat{\theta}_\phi^* = \theta_0$ by assumption (i), and the solution is unique since ϕ is strictly convex and $\partial m / \partial \theta \neq 0$ a.s. by assumption (ii). ■

Holzmann and Eulert (2014) present a different proof of the two results below. We present the following for comparability with the conditional mean case presented in Proposition 1 of the paper.

Proof of Proposition 4. We will show that under assumptions (i) and (ii), $LinLin_B^\alpha \geq LinLin_A^\alpha \Rightarrow \mathcal{F}_t^B \subseteq \mathcal{F}_t^A \ \forall t \Rightarrow E\left[L\left(Y_t, \hat{Y}_t^B\right)\right] \geq E\left[L\left(Y_t, \hat{Y}_t^A\right)\right] \ \forall L \in \mathcal{L}_{GPL}^\alpha$, where $LinLin_j^\alpha \equiv E\left[LinLin\left(Y_t, \hat{Y}_t^j\right)\right]$ for $j \in \{A, B\}$ and $LinLin$ is the "Lin-Lin" loss function in equation (19).

First: we are given that $LinLin_B^\alpha \geq LinLin_A^\alpha$, and assume that $\mathcal{F}_t^A \subseteq \mathcal{F}_t^B \ \forall t$. This means that $\min_{\hat{y}} E\left[LinLin\left(Y_t, \hat{y}\right)|\mathcal{F}_t^A\right] \geq \min_{\hat{y}} E\left[LinLin\left(Y_t, \hat{y}\right)|\mathcal{F}_t^B\right]$ a.s. $\forall t$, and so $E\left[LinLin\left(Y_t, \hat{Y}_t^A\right)|\mathcal{F}_t^A\right] \geq E\left[LinLin\left(Y_t, \hat{Y}_t^B\right)|\mathcal{F}_t^B\right]$ a.s. $\forall t$ by assumption (ii), and $E\left[LinLin\left(Y_t, \hat{Y}_t^A\right)\right] \geq E\left[LinLin\left(Y_t, \hat{Y}_t^B\right)\right]$ by the LIE, which is a contradiction. Thus $LinLin_B^\alpha \geq LinLin_A^\alpha \Rightarrow \mathcal{F}_t^B \subseteq \mathcal{F}_t^A \ \forall t$. Next: Let

$$
\bar{L}^j \equiv E\left[L\left(Y, \hat{Y}^j; \alpha, g_j\right)\right], \ \ j \in \{A, B\}
$$

where $L\left(\cdot, \cdot; \alpha, g_j\right)$ is a GPL loss function defined by g_j, a nondecreasing function. Under assumption (ii) we know that $\hat{Y}^j$ is the solution to $\min_{\hat{y}} E\left[L\left(Y, \hat{Y}^j; \alpha, g_j\right)|\mathcal{F}^j\right]$ where $L \in \mathcal{L}_{GPL}^\alpha$, g_j is a nondecreasing function, and and $j \in \{A, B\}$. It is straightforward to show that $\hat{Y}^j$ then satisfies

26

$\alpha = E\left[\mathbf{1}\left\{Y \leq \hat{Y}^j\right\} | \mathcal{F}^j\right]$. This holds for all possible (conditional) distributions of Y, and from Saerens (2000) and Gneiting (2011b) we know that this implies (by the necessity of GPL loss for optimal quantile forecasts) that $\hat{Y}^j$ then moreover satisfies

$$\hat{Y}^j = \arg\min_{\hat{y}} \ E\left[\left(\mathbf{1}\left\{Y \leq \hat{y}\right\} - \alpha\right)\left(g\left(\hat{y}\right) - g\left(Y\right)\right) | \mathcal{F}^j\right]$$

for any nondecreasing function g. If $\mathcal{F}^B \subseteq \mathcal{F}^A$ then by the LIE we have $\bar{L}^B\left(g\right) \geq \bar{L}^A\left(g\right)$ for any nondecreasing function g. ∎

Proof of Proposition 6.   We again prove this result by showing that $E\left[L\left(F_t^A, Y_t\right)\right] \leq E\left[L\left(F_t^B, Y_t\right)\right]$ for some $L \in \mathcal{L}_{\text{Proper}} \Rightarrow \mathcal{F}_t^B \subseteq \mathcal{F}_t^A \ \forall t \Rightarrow E\left[L\left(F_t^A, Y_t\right)\right] \leq E\left[L\left(F_t^B, Y_t\right)\right] \ \forall \ L \in \mathcal{L}_{\text{Proper}}$. First: we are given that $E\left[L\left(F_t^A, Y_t\right)\right] \leq E\left[L\left(F_t^B, Y_t\right)\right]$, and assume that $\mathcal{F}_t^A \subseteq \mathcal{F}_t^B \ \forall t$. Under assumption (ii), this implies that we can take F_t^B as the data generating process for Y_t. Then $E\left[L\left(F_t^B, Y_t\right) | \mathcal{F}_t^B\right] = E_{F_t^B}\left[L\left(F_t^B, Y_t\right) | \mathcal{F}_t^B\right] \leq E_{F_t^B}\left[L\left(F_t^A, Y_t\right) | \mathcal{F}_t^B\right] \ \forall t$ by assumption (ii) and the propriety of L. By the LIE this implies $E\left[L\left(F_t^B, Y_t\right)\right] \leq E\left[L\left(F_t^A, Y_t\right)\right]$ which is a contradiction. Thus $E\left[L\left(F_t^A, Y_t\right)\right] \leq E\left[L\left(F_t^B, Y_t\right)\right]$ for some $L \in \mathcal{L}_{\text{Proper}} \Rightarrow \mathcal{F}_t^B \subseteq \mathcal{F}_t^A \ \forall t$. Next, using similar logic to above, given $\mathcal{F}_t^B \subseteq \mathcal{F}_t^A$ we have that $E\left[L\left(F_t^A, Y_t\right)\right] \leq E\left[L\left(F_t^B, Y_t\right)\right]$ for any $L \in \mathcal{L}_{\text{Proper}}$, completing the proof. ∎

Proof of Proposition 8.   (a) Recall the forms of these two loss functions from equations (4) and (18). Then the expected loss w.r.t. distribution F_t from a convex combination of these loss functions is

$$
\begin{aligned}
E_{F_t}\left[L\left(Y_t, \hat{y}\right)\right] \ = \ & \lambda E_{F_t}\left[\phi\left(Y_t\right)\right] - \lambda\phi\left(\hat{y}\right) - \lambda\phi'\left(\hat{y}\right)\left(E_{F_t}\left[Y_t\right] - \hat{y}\right) \\
& + \left(1 - \lambda\right)\left(E_{F_t}\left[\mathbf{1}\left\{Y_t \leq \hat{y}\right\}\right] - 1/2\right)g\left(\hat{y}\right) \\
& + \left(1 - \lambda\right)E_{F_t}\left[\left(\mathbf{1}\left\{Y_t \leq \hat{y}\right\} - 1/2\right)g\left(Y_t\right)\right]
\end{aligned}
$$

And the first derivative is

$$\frac{\partial}{\partial\hat{y}}E_{F_t}\left[L\left(Y, \hat{y}\right)\right] = -\lambda\phi''\left(\hat{y}\right)\left(E_{F_t}\left[Y_t\right] - \hat{y}\right) + \left(1 - \lambda\right)\left(E_{F_t}\left[\mathbf{1}\left\{Y_t \leq \hat{y}\right\}\right] - 1/2\right)g'\left(\hat{y}\right)$$

using assumption (i) that F_t is continuous. Then note that $E_{F_t}\left[\mathbf{1}\left\{Y_t \leq \hat{y}\right\}\right] \equiv F_t\left(\hat{y}\right)$, and recall that F_t is symmetric $\Rightarrow E_{F_t}\left[Y_t\right] = Median_{F_t}\left[Y_t\right] \Rightarrow F_t\left(E\left[Y_t | \mathcal{F}_t\right]\right) = 1/2$. Thus $\hat{Y}_t^* = E_{F_t}\left[Y_t\right]$ is a

solution to the optimization problem:

$$-\lambda \phi'' \left(E_{F_t}\left[Y_t\right]\right)\left(E_{F_t}\left[Y_t\right] - E_{F_t}\left[Y_t\right]\right) + (1-\lambda)\left(E_{F_t}\left[\mathbf{1}\left\{Y_t \le E_{F_t}\left[Y_t\right]\right\}\right] - 1/2\right)g'\left(E_{F_t}\left[Y_t\right]\right) = 0$$

Note that this result holds whether or not the target variable is truly symmetrically distributed.

(b) We will show that under assumptions (i)–(iii) , $MSE_B \ge MSE_A \Rightarrow \mathcal{F}_t^B \subseteq \mathcal{F}_t^A \ \forall t$, $MAE_B \ge MAE_A \Rightarrow \mathcal{F}_t^B \subseteq \mathcal{F}_t^A \ \forall t$, and $\mathcal{F}_t^B \subseteq \mathcal{F}_t^A \ \forall t \Rightarrow E\left[L\left(Y_t, \hat{Y}_t^B\right)\right] \ge E\left[L\left(Y_t, \hat{Y}_t^A\right)\right] \ \forall L \in \mathcal{L}_{Breg \times GPL}$. First implication: We are given that $MSE_B \ge MSE_A$, and assume that $\mathcal{F}_t^A \subseteq \mathcal{F}_t^B \ \forall t$. This means that $\min_{\hat{y}} \ E\left[(Y_t - \hat{y})^2 \,|\mathcal{F}_t^A\right] \ge \min_{\hat{y}} \ E\left[(Y_t - \hat{y})^2 \,|\mathcal{F}_t^B\right]$ a.s. $\forall t$. Since the quadratic loss function is in $\mathcal{L}_{Breg \times GPL}$, then by part (a) and assumption (iii) we have $E\left[\left(Y_t - \hat{Y}_t^A\right)^2 |\mathcal{F}_t^A\right] \ge E\left[\left(Y_t - \hat{Y}_t^B\right)^2 |\mathcal{F}_t^B\right]$ a.s. $\forall t$, and $E\left[\left(Y_t - \hat{Y}_t^A\right)^2\right] \ge E\left[\left(Y_t - \hat{Y}_t^B\right)^2\right]$ by the law of iterated expectations, which is a contradiction. Thus $MSE_B \ge MSE_A \Rightarrow \mathcal{F}_t^B \subseteq \mathcal{F}_t^A \ \forall t$. The same reasoning applies for the implication $MAE_B \ge MAE_A \Rightarrow \mathcal{F}_t^B \subseteq \mathcal{F}_t^A \ \forall t$. Finally, consider the third implication. The expected loss difference is

$$
\begin{aligned}
E\left[L\left(Y_t, \hat{Y}_t^A\right) - L\left(Y_t, \hat{Y}_t^B\right)\right] &= \lambda E\left[L_{Breg}\left(Y_t, \hat{Y}_t^A\right) - L_{Breg}\left(Y_t, \hat{Y}_t^B\right)\right] \\
&\quad + (1-\lambda)E\left[L_{GPL}\left(Y_t, \hat{Y}_t^A\right) - L_{GPL}\left(Y_t, \hat{Y}_t^B\right)\right]
\end{aligned}
$$

where $L_{Breg} \in \mathcal{L}_{Bregman}$, $L_{GPL} \in \mathcal{L}_{GPL}^{1/2}$, and $\lambda \in [0,1]$. Noting that assumptions (i)–(iii) satisfy those of Proposition 1, we then have $\mathcal{F}_t^B \subseteq \mathcal{F}_t^A \ \forall t \Rightarrow E\left[L_{Breg}\left(Y_t, \hat{Y}_t^A\right) - L_{Breg}\left(Y_t, \hat{Y}_t^B\right)\right] \le 0 \ \forall L \in \mathcal{L}_{Bregman}$. Similarly, from the proof of Proposition 4 we also have $\mathcal{F}_t^B \subseteq \mathcal{F}_t^A \ \forall t \Rightarrow E\left[L_{GPL}\left(Y_t, \hat{Y}_t^A\right) - L_{GPL}\left(Y_t, \hat{Y}_t^B\right)\right] \le 0 \ \forall L \in \mathcal{L}_{GPL}^{1/2}$. Since $\lambda \in [0,1]$ we then have $E\left[L\left(Y_t, \hat{Y}_t^A\right) - L\left(Y_t, \hat{Y}_t^B\right)\right] \le 0$ for any $L \in \mathcal{L}_{Breg \times GPL}$.

(c) The proof of this negative result requires only an example. This can be constructed using methods similar to those for Propositions 2 and 5, and is omitted in the interest of brevity. ∎

Derivations for Example 1:

The first-order condition for the optimal parameter θ is:

$$
\begin{aligned}
0 &= \frac{\partial}{\partial \theta} E\left[L\left(Y, m\left(X;\theta\right);\phi\right)\right] \\
&= E\left[\phi''\left(m\left(X;\theta\right)\right)\left(E\left[Y|X\right] - m\left(X;\theta\right)\right)\frac{\partial m\left(X;\theta\right)}{\partial \theta}\right] \qquad (40) \\
&= 2E\left[\exp\left\{a\left(\alpha + \beta X\right)\right\}\left(X^2 - \alpha - \beta X\right)\left[1, X\right]'\right]
\end{aligned}
$$

So the two first-order conditions are:

$$
0 = E\left[\exp\left\{a\left(\alpha + \beta X\right)\right\}X^2\right] - \alpha E\left[\exp\left\{a\left(\alpha + \beta X\right)\right\}\right] - \beta E\left[\exp\left\{a\left(\alpha + \beta X\right)\right\}X\right] \qquad (41)
$$

$$
0 = E\left[\exp\left\{a\left(\alpha + \beta X\right)\right\}X^3\right] - \alpha E\left[\exp\left\{a\left(\alpha + \beta X\right)\right\}X\right] - \beta E\left[\exp\left\{a\left(\alpha + \beta X\right)\right\}X^2\right]
$$

Using properties of the Normal distribution we obtain the key moments from the above expressions:

$$
\begin{aligned}
E\left[\exp\left\{a\left(\alpha + \beta X\right)\right\}\right] &= \exp\left\{a\left(\alpha + \beta\mu\right) + a^2\frac{\beta^2}{2}\sigma^2\right\} \qquad (42) \\
E\left[\exp\left\{a\left(\alpha + \beta X\right)\right\}X\right] &= \exp\left\{a\left(\alpha + \beta\mu\right) + a^2\frac{\beta^2}{2}\sigma^2\right\}\left(\mu + a\beta\sigma^2\right) \\
E\left[\exp\left\{a\left(\alpha + \beta X\right)\right\}X^2\right] &= \exp\left\{a\left(\alpha + \beta\mu\right) + a^2\frac{\beta^2}{2}\sigma^2\right\}\left(\sigma^2 + \left(\mu + a\beta\sigma^2\right)^2\right) \\
E\left[\exp\left\{a\left(\alpha + \beta X\right)\right\}X^3\right] &= \exp\left\{a\left(\alpha + \beta\mu\right) + a^2\frac{\beta^2}{2}\sigma^2\right\}\left(\mu + a\beta\sigma^2\right)\left(3\sigma^2 + \left(\mu + a\beta\sigma^2\right)^2\right)
\end{aligned}
$$

Table 1: Optimal linear approximation example

	Exponential Bregman parameter (a)		
	-0.5	0	0.25
$\hat{\alpha}_a^*$	0.75	0.00	-3.00
$\hat{\beta}_a^*$	1.00	2.00	4.00

This table presents the optimal intercept ($\hat{\alpha}_a^*$) and slope ($\hat{\beta}_a^*$) parameters from linear approximations to a nonlinear conditional mean function, for three different values of the "exponential Bregman" loss function parameter, a.

Table 2: Average MSE and QLIKE loss for different estimation methods

Evaluation loss function	QLIKE		MSE	
Estimation loss function	*QLIKE*	*MSE*	*QLIKE*	*MSE*
100	1.505	1.509	4.535	4.326
500	1.428	1.435	4.277	4.239
1000	1.412	1.418	4.228	4.206
∞	1.399	1.401	4.179	4.169
γ_0^*	0.912	0.938	0.912	0.938
γ_1^*	0.093	0.071	0.093	0.071

Notes: This table presents the average out-of-sample loss from a volatility forecast from an ARCH(1) model (equation 37) estimated by minimizing either the QLIKE loss function or the quadratic loss function (MSE) over a rolling window of $T \in \{100, 500, 1000\}$ observations. The bottom row of the top panel presents the average loss when the parameters are set to the population limits, these limiting parameters are presented in the bottom two rows of the table.

Table 3: Summary Statistics

Panel A: Consensus forecasts

	Actual	SPF	Michigan
Mean	2.633	3.246	3.196
Standard deviation	1.202	1.282	0.729
Minimum	-1.930	1.565	0.900
Maximum	5.662	8.058	6.700

Panel B: Individual forecasts

	Actual	Forecaster 20	Forecaster 506	Forecaster 528
Mean	4.213	3.295	1.339	1.542
Standard deviation	3.458	1.369	1.243	1.243
Minimum	-13.668	0.800	-2.600	-2.000
Maximum	16.645	11.400	3.829	3.600

Notes: This table presents summary statistics on realized inflation and inflation forecasts. Panel A considers one-year consensus forecasts, in percent, of annual US CPI inflation from the Survey of Professional Forecasters and from the Thomson Reuters/University of Michigan Survey of Consumers. Panel B considers one-quarter forecasts from individual respondents to the Survey of Professional Forecasters, of US CPI inflation, annualized, in percent.
Figure 1: *Various Bregman loss functions. The left column presents four elements of the "homogeneous Bregman" family, and the right column presents four elements of the "exponential Bregman" family. The squared error loss function is also presented in each panel. In all cases the value for ŷ ranges from -1 to 5, and the value of y is set at 2.*
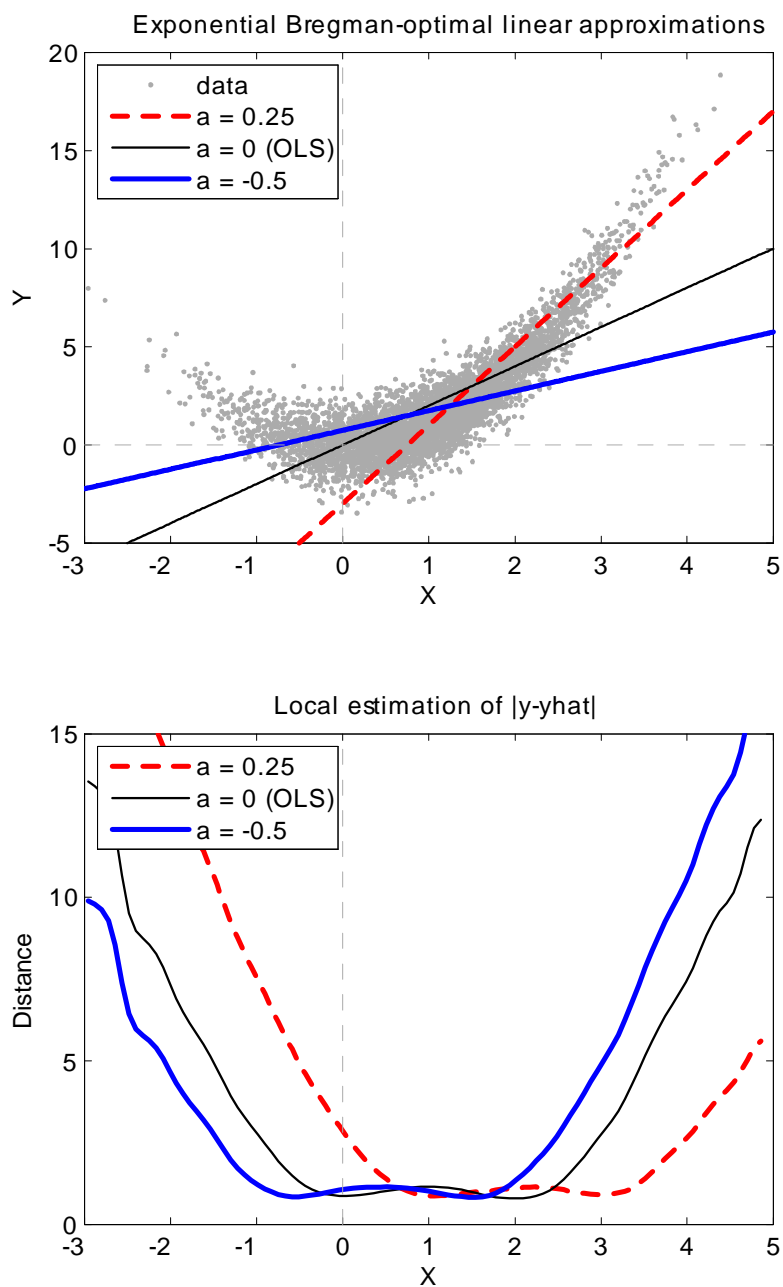

Figure 2: *The top panel presents the optimal linear approximations to a nonlinear DGP based on the exponential Bregman loss function for three choices of "shape" parameter; the choice a=0 corresponds to quadratic loss, and the fit is then the same as that obtained by OLS. The lower panel presents a simple nonparametric estimate of the distance between the realization and the (linear) forecast as a function of the predictor variable (X), for the three loss function parameters.*
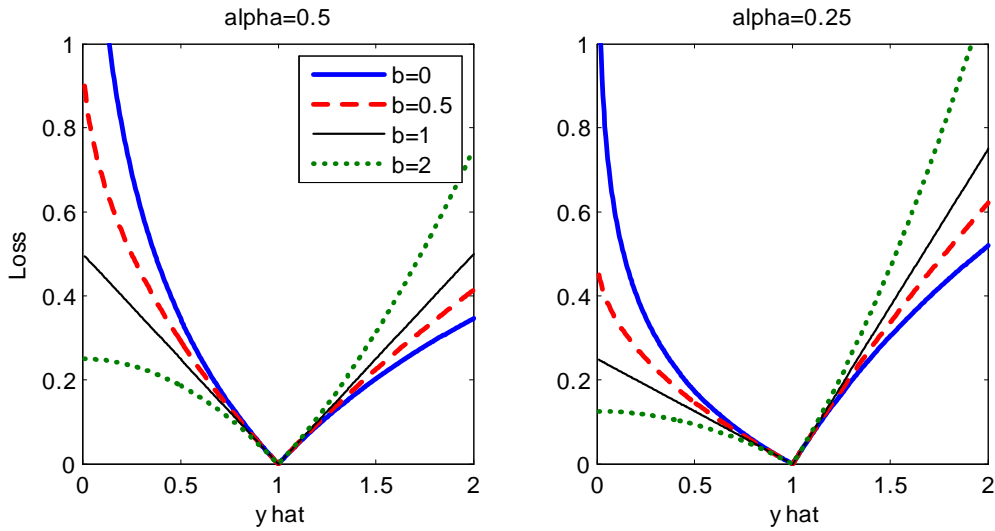

Figure 3: *Various homogenous GPL loss functions, with $\alpha = 0.5$ (left panel) and $\alpha = 0.25$ (right panel). The "Lin-Lin" (or "tick") loss function is obtained when $b = 1$. In both cases the value for $\hat{y}$ ranges from 0 to 2, and the value of y is set at 1.*
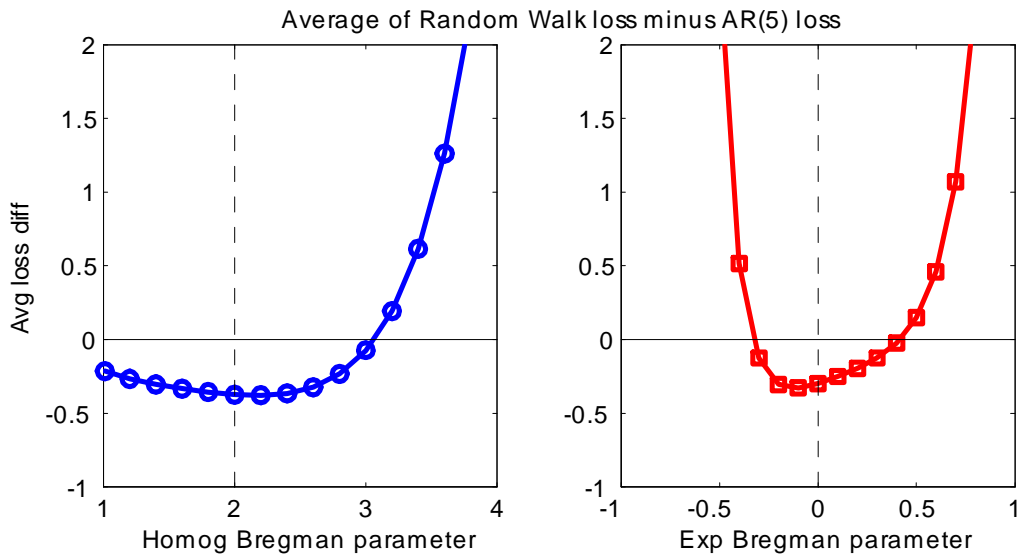

Figure 4: *Average loss from a random walk forecast minus that from an estimated AR(5) forecast, for various homogeneous (left panel) and exponential (right panel) Bregman loss functions.*
Figure 5: *Average loss from a AR-constant volatility forecsast minus that from a constant mean-GARCH forecast for various GPL loss functions. (Lin-Lin loss is marked with a vertical line at 1.) The left panel is for the 0.25 quantile, and the right panel is for the 0.05 quantile.*

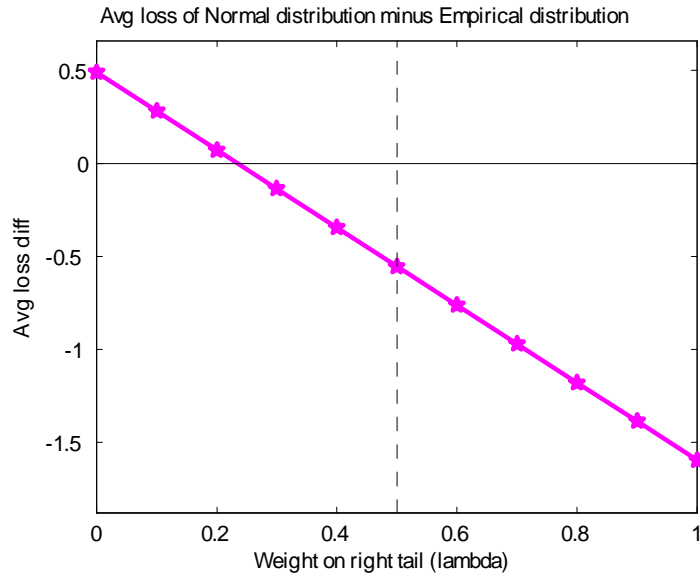

Figure 6: *Average wCRSP loss from a Normal distribution forecast minus that from an empirical distribution forecast based on 100 observations. The x-axis plots different weights on the left/right tail, with equal weight at 0.5, indicated with a vertical line.*
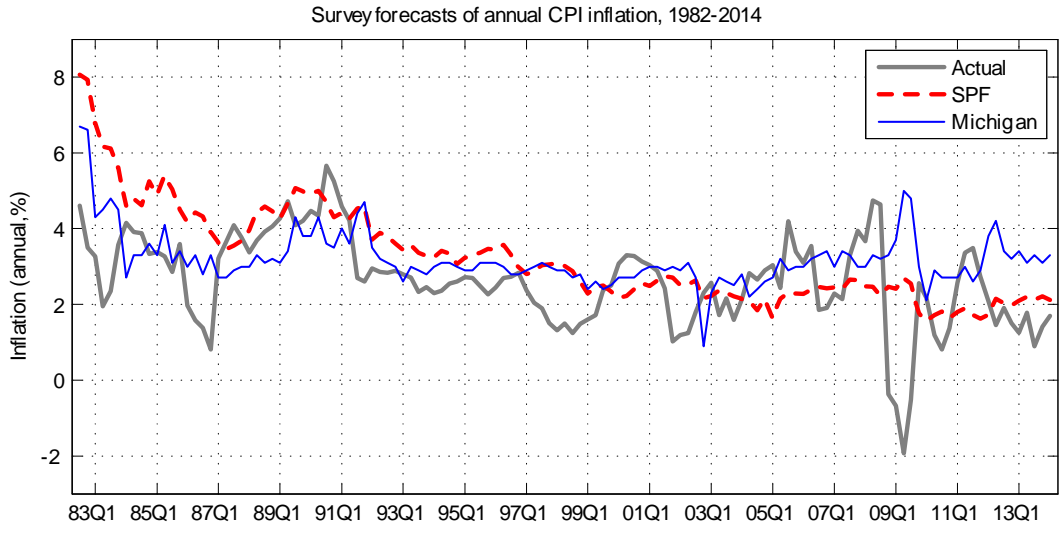

Figure 7: *Time series of actual and predicted annual US CPI inflation, updated quarterly, over the period 1982Q3–2014Q1. The inflation forecasts come from the Survey of Professional Forecasters and the Michigan survey of consumers.*
Figure 8: *Differences in average losses between two forecasts, for a range of loss function parameters. The "homogeneous Bregman" loss function is in the left column, and the "exponential Bregman" loss function is in the right column. The squared-error loss function is nested at 2 and 0 for these loss functions, and is indicated by a vertical line. The top row compares the consensus forecast from the Survey of Professional Forecasters and the Michigan survey of consumers; the lower two rows compare individual forecasters from the Survey of Professional Forecasters.*
