Volatility forecast comparison using imperfect volatility proxies

Andrew J. Patton

Department of Economics, Duke University, USA
Oxford-Man Institute of Quantitative Finance, University of Oxford, UK

Abstract

The use of a conditionally unbiased, but imperfect, volatility proxy can lead to undesirable outcomes in standard methods for comparing conditional variance forecasts. We motivate our study with analytical results on the distortions caused by some widely used loss functions, when used with standard volatility proxies such as squared returns, the intra-daily range or realised volatility. We then derive necessary and sufficient conditions on the functional form of the loss function for the ranking of competing volatility forecasts to be robust to the presence of noise in the volatility proxy, and derive some useful special cases of this class of “robust” loss functions. The methods are illustrated with an application to the volatility of returns on IBM over the period 1993 to 2003.

1. Introduction

Many forecasting problems in economics and finance involve a variable of interest that is unobservable, even ex post. The most prominent example of such a problem is the forecasting of volatility for use in financial decision making. Other problems include forecasting the true rates of inflation, GDP growth or unemployment (not simply the announced rates); forecasting trade intensities; and forecasting default probabilities or ‘crash’ probabilities. While evaluating and comparing economic forecasts is a well-studied problem, dating back at least to Cowles (1933), if the variable of interest is latent then the problem of forecast evaluation and comparison becomes more complicated.\(^1\)

This complication can be resolved, at least partly, if an unbiased estimator of the latent variable of interest is available. In volatility forecasting, for example, the squared return on an asset over the period \(t\) (assuming a zero mean return) can be interpreted as a conditionally unbiased estimator of the true unobserved conditional variance of the asset over the period \(t\).\(^2\) Many of the standard methods for forecast evaluation and comparison, such as the Mincer and Zarnowitz (1969) regression and the Diebold and Mariano (1995) and West (1996) tests, can be shown to be applicable when such a conditionally unbiased proxy is used, see Hansen and Lunde (2006) for example. However, it is not true that using a conditionally unbiased proxy will always lead to the same outcome as if the true latent variable were used: Andersen and Bollerslev (1998) and Andersen et al. (2005), amongst others, study the reduction in finite-sample power of tests based on noisy volatility proxies; we focus, like Hansen and Lunde (2006), on distortions in the rankings of competing forecasts that can arise when using a noisy volatility proxy in some commonly used tests for forecast comparison.

For example, in the volatility forecasting literature numerous authors have expressed concern that a few extreme observations may have an unduly large impact on the outcomes of forecast evaluation and comparison tests, see Bollerslev and Ghysels (1994), Andersen et al. (1999) and Poon and Granger (2003) amongst others. One common response to this concern is to employ forecast loss functions that are “less sensitive” to large observations than the usual squared forecast error loss function, such as absolute error or proportional error loss functions. In

---

\(^1\) Matlab code used in this paper is available from http://econ.duke.edu/~ap172/code.html.

\(^2\) For recent surveys of the forecast evaluation literature see Clements (2005) and West (2006). For recent surveys of the volatility forecasting literature, see Andersen et al. (2006), Poon and Granger (2003) and Shephard (2005).
this paper we show analytically that such approaches can lead to incorrect inferences and the selection of inferior forecasts over better forecasts.

We focus on volatility forecasting as a specific case of the more general problem of latent variable forecasting. In Section 5 we discuss the extension of our results to other latent variable forecasting problems. Our research builds on work by Andersen and Bollerslev (1998), Meddahi (2001) and Hansen and Lunde (2006), who were among the first to analyse the problems introduced by the presence of noise in a volatility proxy. This paper extends the existing literature in two important directions, discussed below.

Firstly, we derive explicit analytical results for the distortions that may arise when some common loss functions are employed, considering the three most commonly used volatility proxies: the daily squared return, the intra-daily range and a realised variance. We show that these distortions can be large, even for the daily squared return, the intra-daily range and a realised variance. The distortions vary greatly with the choice of loss function, thus providing a theoretical explanation for the widespread finding of conflicting rankings of volatility forecasts when “non-robust” loss functions (defined precisely in Section 2) are used in applied work, see Lamoureux and Lastrapes (1993), Hamilton and Susmel (1994), Bollerslev and Chyseis (1994) and Hansen and Lunde (2005), amongst many others.3

Secondly, we provide necessary and sufficient conditions on the functional form of the loss function to ensure that the ranking of various forecasts is preserved when using a noisy volatility proxy. These conditions are related to those of Gourieroux et al. (1984) for quasi-maximum likelihood estimation. Interestingly, we find that there are an infinite number of loss functions that satisfy these conditions, and that these loss functions differ in meaningful ways (such as the penalty applied to over-prediction versus under-prediction). Thus our class of “robust” loss functions is not simply the quadratic loss function or minor variations thereof.

The canonical problem in point forecasting is to find the forecast that minimises the expected loss, conditional on time t information. That is,

\[ \hat{Y}_{t+h|t} = \arg\min_{\hat{Y} \in \mathbb{Y}} E \left[ L \left( Y_{t+h|t}, \hat{Y} \right) | \mathcal{F}_t \right] \]

where \( Y_{t+h|t} \) is the variable of interest, \( L \) is the forecast user’s loss function, \( \mathbb{Y} \) is the set of possible forecasts, and \( \mathcal{F}_t \) is the time t information set. Starting with the assumption that the forecast user is interested in the conditional variance, we effectively take the solution of the optimisation problem above (the conditional variance) as given, and consider the loss functions that will generate the desired solution. This approach is unusual in the economic forecasting literature: the more common approach is to take the forecast user’s loss function as given and derive the optimal forecast for that loss function; related papers here are Granger (1969), Engle (1993), Christoffersen and Diebold (1997), Christoffersen and Jacobs (2004) and Patton and Timmermann (2007), amongst others. The fact that we know the forecast user desires a variance forecast places limits on the class of loss functions that may be used for volatility comparison, ruling out some choices previously used in the literature. However we show that the class of “robust” loss functions still admits a wide variety of loss functions, allowing much flexibility in representing volatility forecast users’ preferences.

One practical implication of this paper is that the stated goal of forecasting the conditional variance is not consistent with the use of some loss functions when an imperfect volatility proxy is employed. However, these loss functions are not inherently invalid or inappropriate: if the forecast user’s preferences are indeed described by an “non-robust” loss function, then this simply implies that the object of interest to that forecast user is not the conditional variance but rather some other quantity.4 In academic research the preferences of the end-user of the forecast are often unknown, and a common response to this is to select forecasts based on their average distance, somehow measured, to the true latent conditional variance. In such cases, the methods outlined in this paper can be applied to identify the forecast that is closest to the true conditional variance by using imperfect volatility proxy and a “robust” loss function.

The remainder of this paper is as follows. In Section 2 we analytically consider volatility forecast comparison tests using an imperfect volatility proxy, showing the problems that arise when using some common loss functions. We initially consider using squared daily returns as the proxy, and then consider using the range and realised variance. In Section 3 we provide necessary and sufficient conditions on the functional form of a loss function for the ranking of competing volatility forecasts to be robust to the presence of noise in the volatility proxy, and derive some useful special cases of this class of robust loss functions. One of these special cases is a parametric family of loss functions that nests two of the most widely used loss functions in the literature, namely the MSE and QLIKE loss functions (defined in Eqs. (5) and (6) below). In Section 4 we present an empirical illustration using two widely used volatility forecasting methods, and in Section 5 we conclude and suggest extensions. All proofs and derivations are provided in Appendix.

1.1. Notation

Let \( r_t \) be the variable whose conditional variance is of interest, usually a daily or monthly asset return in the volatility forecasting literature. The information set used in defining the conditional variance of interest is denoted \( \mathcal{F}_{t-1} \), which is assumed to contain \( \sigma_r^2 \). We will assume throughout that \( \mathbb{E}[r_{t+1} | \mathcal{F}_{t-1}] \equiv V_{-1}[r_t] = \sigma_r^2 \). We will assume furthermore that \( \mathbb{E}[r_{t+1}^2 | \mathcal{F}_{t-1}] = V_{-1}[r_t^2] = \sigma_r^2 \). Let \( \varepsilon_t \equiv r_t / \sigma_r \) denote the ‘standardised return’. Let a forecast of the conditional variance of \( r_t \) be denoted \( h_{t+1} \), or \( h_t \), if there is more than one forecast under analysis. We will take forecasts as ‘primitive’, and not consider the specific models and estimators that may have generated the forecasts. The loss function of the forecast user is \( L : \mathbb{R}_+ \times \mathcal{H} \rightarrow \mathbb{R}_+ \), where the first argument of \( L \) is \( \sigma_r^2 \) or some proxy for \( \sigma_r^2 \), denoted \( \hat{\sigma}_r^2 \), and the second is \( h_t \), or \( h_{t+1} \), the non-negative and positive parts of the real line respectively, and \( \mathcal{H} \) is a compact subset of \( \mathbb{R}_+ \). Commonly used volatility proxies are the squared return, \( r_t^2 \), realised volatility, \(RV_t \), and the range, \( RG_t \). Optimal forecasts \( \hat{\alpha} \) given loss function and proxy are denoted \( h_{\hat{\alpha}}^* \) and are defined as:

\[ h_{\hat{\alpha}}^* \equiv \arg\min_{h \in \mathcal{H}} E \left[ L \left( \hat{\sigma}_r^2, h \right) | \mathcal{F}_{t-1} \right] . \]

3 All of the results in this paper apply directly to the problem of forecasting integrated variance (IV), which Andersen et al. (2010), amongst others, argue is a more “relevant” notion of variability. We focus on the problem of conditional variance forecasting due to its prevalence in applied work in the past two decades. If we take expected IV rather than the conditional variance as the latent object of interest, then we only require that an unbiased realised variance estimator is available for the results to go through. In the presence of jumps in the price process, quadratic variation (QV) is a more appropriate measure of risk, and a similar extension is possible.

4 For example, the utility of realised returns on a portfolio formed using a volatility forecast, or the profits obtained from an option trading strategy based on a volatility forecast, see West et al. (1993) and Engle et al. (1993) for example, define economically meaningful loss functions, even though the optimal forecasts under those loss functions will not generally be the true conditional variance.
2. Volatility forecast comparison using an imperfect volatility proxy

We consider volatility forecast comparisons based on expected loss, or distance to the true conditional variance. These comparisons can be implemented in finite samples using the tests of Diebold and Mariano (1995) and West (1996), (henceforth DMW). If we define \( u_{t,t} = L(\sigma^2_t, h_t) \), where \( L \) is the forecast user's loss function, and let \( d_t = u_{1,t} - u_{2,t} \), then a DMW test of equal predictive accuracy can be conducted as a simple Wald test that \( E[d_t] = 0 \).

Of primary interest is whether the feasible ranking of two forecasts obtained using an imperfect volatility proxy is the same as the infeasible ranking that would be obtained using the unobservable true conditional variance. In such a case we are able to compare average forecast accuracy even though the variable of interest is unobservable. We define loss functions that yield such an equivalence as “robust”:

**Definition 1.** A loss function, \( L \), is “robust” if the ranking of any two (possibly imperfect) volatility forecasts, \( h_{1,t} \) and \( h_{2,t} \), by expected loss is the same whether the ranking is done using the true conditional variance, \( \sigma^2_t \), or some conditionally unbiased volatility proxy, \( \hat{\sigma}^2_t \). That is,

\[
E \left[ L(\sigma^2_t, h_{1,t}) \right] \geq E \left[ L(\sigma^2_t, h_{2,t}) \right]
\]

\[
\Rightarrow E \left[ L(\hat{\sigma}^2_t, h_{1,t}) \right] \geq E \left[ L(\hat{\sigma}^2_t, h_{2,t}) \right]
\]

for any \( \hat{\sigma}^2_t \) s.t. \( E[\hat{\sigma}^2_t|F_{t-1}] = \sigma^2_t \).

Madders (2001) showed that the ranking of forecasts on the basis of the \( R^2 \) from the Mincer–Zarnowitz regression:

\[
\hat{\sigma}^2_t = \beta_0 + \beta_1 h_{it} + e_{it}
\]

is robust to noise in \( \hat{\sigma}^2_t \). Hansen and Lunde (2006) showed that the \( R^2 \) from a regression of \( \log(\hat{\sigma}^2_t) \) on a constant and \( \log(h_i) \) is not robust to noise, and showed more generally that a sufficient condition for a loss function to be robust is that \( \partial^2 L(\sigma^2_t, h)/\partial(\sigma^2)^2 \) does not depend on \( h \) in Section 3. We generalise this result by providing necessary and sufficient conditions for a loss function to be robust.

It is worth noting that although the ranking obtained from a robust loss function will be invariant to noise in the proxy, the actual level of expected loss obtained using a proxy will be larger than that which would be obtained when using the true conditional variance. This point was compellingly presented in Andersen and Bollerslev (1998) and Andersen et al. (2004). Andersen et al. (2005) provide a method to estimate the distortion in the level of expected loss and thereby obtain an estimator of the level of expected loss that would be obtained using the true latent variable of interest.

It follows directly from the definition of a robust loss function that the true conditional variance is the optimal forecast (we formally show this in the proof of Proposition 1), and thus a necessary condition for a loss function to be robust to noise is that the true conditional variance is the optimal forecast. In this section we determine whether this condition holds for some common loss functions, and analytically characterise the distortion for those cases where it is violated.

A common response to the concern that a few extreme observations drive the results of volatility forecast comparison studies is to employ alternative measures of forecast accuracy to the usual MSE loss function, see Pagan and Schwert (1990), Bollerslev and Ghysels (1994); Bollerslev et al. (1994), Diebold and Lopez (1996), Andersen et al. (1999), Poon and Granger (2003) and Hansen and Lunde (2005), for example. A collection of loss functions employed in the literature on volatility forecast evaluation is presented below.

In the next two subsections we will study the properties of these loss functions and show that for almost all choices of volatility proxy most of these loss functions are not robust and can lead to incorrect rankings of volatility forecasts.

**MSE**:

\[
\text{MSE} : L(\hat{\sigma}^2_t, h) = (\hat{\sigma}^2_t - h)^2
\]

**QLIKE**:

\[
\text{QLIKE} : L(\hat{\sigma}^2_t, h) = \log h + \hat{\sigma}^2_t
\]

**MSE-LOG**:

\[
\text{MSE-LOG} : L(\hat{\sigma}^2_t, h) = (\log \hat{\sigma}^2_t - \log h)^2
\]

**MSE-SD**:

\[
\text{MSE-SD} : L(\hat{\sigma}^2_t, h) = (\hat{\sigma}^2_t - \sqrt{h})^2
\]

**MSE-prop**:

\[
\text{MSE-prop} : L(\hat{\sigma}^2_t, h) = (\hat{\sigma}^2_t - h)^2
\]

**MAE**:

\[
\text{MAE} : L(\hat{\sigma}^2_t, h) = |\hat{\sigma}^2_t - h|
\]

**MAE-LOG**:

\[
\text{MAE-LOG} : L(\hat{\sigma}^2_t, h) = |\log \hat{\sigma}^2_t - \log h|
\]

**MAE-SD**:

\[
\text{MAE-SD} : L(\hat{\sigma}^2_t, h) = |\hat{\sigma}^2_t - \sqrt{h}|
\]

**MAE-prop**:

\[
\text{MAE-prop} : L(\hat{\sigma}^2_t, h) = |\hat{\sigma}^2_t - h|
\]

2.1. Using squared returns as a volatility proxy

In this section we will focus on the use of daily squared returns for volatility forecast evaluation, and in Section 2.2 we will examine the use of realised volatility and the range. We will derive our results under three assumptions for the conditional distribution of daily returns:

\[
r_{t} \mid F_{t-1} \sim \begin{cases} \text{Student's t}(0, \sigma^2_t, v) & \\
N(0, \sigma^2_t) & \end{cases}
\]

where \( F_t(0, \sigma^2_t) \) is some unspecified distribution with mean zero and variance \( \sigma^2_t \), and Student’s \( t(0, \sigma^2_t, v) \) is a Student’s \( t \) distribution with mean zero, variance \( \sigma^2_t \) and \( v \) degrees of freedom.

---

5 The key difference between the approaches of Diebold and Mariano (1995) and West (1996) is that the latter explicitly allows for forecasts that are based on estimated parameters, whereas the null of equal predictive accuracy is based on population parameters, see West (2006). The problems we identify below arise even in the absence of estimation error in the forecasts, thus our treatment of the forecasts as primitive, and so for our purposes these two approaches coincide.

6 Our use of the adjective “robust” is related, though not equivalent, to its use in estimation theory, where it applies to estimators that insensitive/less sensitive to the presence of outliers in the data, see Huber (1981) for example. A “robust” loss function, in the sense of Definition 1, will generally not be robust to the presence of outliers.

7 In recent work Giacomini and White (2006) propose ranking forecasts by expected loss conditional on some information set \( g_t \), rather than by unconditional expected loss as in Definition 1. The numerical examples provided below will differ in this more general case, of course, however the theoretical results in this paper go through if \( g_t \subseteq \mathcal{F}_{t-1} \), which is true for all of the examples considered by Giacomini and White (2006).

8 Some of these loss functions are called different names by different authors: MSE-prop is also known as “heteroskedasticity-adjusted MSE (HMSE)”; MAE-prop is also known as “mean absolute percentage error (MAPE) or as “heteroskedasticity-adjusted MAE (HMAE)”.
In all cases it is clear that \( E_{-1}[r_t^2] = \sigma_t^2 \), and so the squared daily return is a valid volatility proxy.

It is trivial to show that the MSE loss function generates an optimal forecast equal to the conditional variance: \( h_t^* = E_{-1}[r_t^2] = \sigma_t^2 \), and thus satisfies the necessary condition for robustness. Further, the MSE loss function also satisfies the sufficient condition of Hansen and Lunde (2006), and thus MSE is a “robust” loss function. Another commonly used loss function is the MSE loss function on standard deviations rather than variances, MSE-SD, see Eq. (8). The motivation for this loss function is that taking square root of the two arguments of the squared-error loss function shrinks the larger values towards zero, reducing the impact of the most extreme values of \( r_t \). However it also leads to an incorrect volatility forecast being selected as optimal:

\[
h_t^* = \arg \min_{h \in H} E_{-1} \left[ (r_t - \sqrt{h})^2 \right]
\]

\[
\text{FOC} = \frac{\partial}{\partial h} E_{-1} \left[ (r_t - \sqrt{h})^2 \right] = 0 \quad \text{hence } h_t^* = E_{-1}[r_t^2] = \sigma_t^2
\]

so \( h_t^* = (E_{-1}[|r_t|^2])^{1/2} \)

\[
= \left[ \frac{\nu - 2}{\pi} \left( \frac{\nu - 1}{2} \right) \left( \frac{1}{\nu} \right)^{\nu/2} \right]^{1/2} \sigma_t^2, \quad \text{if } r_t | \mathcal{F}_{t-1} \sim \text{Student's t} \left( 0, \sigma_t^2, \nu \right), \nu > 2
\]

\[
= \left[ \frac{2}{\pi} \sigma_t^2 \right]^{1/2} \approx 0.54 \sigma_t^2, \quad \text{if } r_t | \mathcal{F}_{t-1} \sim \text{N} \left( 0, \sigma_t^2 \right).
\]

This distortion is present even under Gaussianity, and excess kurtosis in asset returns exacerbates the distortion: For example, if returns follow the Student’s t distribution with six degrees of freedom then the coefficient on \( \sigma_t^2 \) in the above expression is 0.56.

As mentioned in the Introduction, if the forecast user’s loss function truly is the square of the difference between the absolute return and the square root of the forecast, then the “distortion” in the optimal forecast above is desirable, as this is the forecast that minimises his/her expected loss. However, if the goal is to find the forecast that is closest to the true conditional variance, then this distortion in the optimal forecast can lead to an incorrect ranking of competing forecasts. Thus the MSE-SD loss function is not consistent with the goal of ranking volatility forecasts by their distance to the true conditional variance when using the squared return as the volatility proxy: either the proxy has to be re-scaled by a term that depends critically on the underlying conditional distribution of returns, or, more simply, a different loss function must be chosen.

The corresponding calculations for the remaining loss functions in Eqs. (5) to (13) are provided in Patton (2006), and the results are summarised in Table 1. This table shows that the degree of distortion in the optimal forecast according to some of the loss functions used in the literature can be substantial. Under normality the optimal forecast under these loss functions ranges from about one quarter of the true conditional variance to three times the true conditional variance. If returns exhibit excess conditional kurtosis then the range of optimal forecasts from these loss functions is even wider.

Table 1 provides a theoretical explanation for the widespread finding of conflicting rankings of volatility forecasts when non-robust loss functions are used in applied work. Lamoureux and Lastrapes (1993), Hamilton and Susmel (1994), Bollerslev and

---

9 This distortion remains if the target is instead the conditional standard deviation, as the absolute return is not an unbiased proxy for that quantity.

10 Analytical and empirical results on the range and “realised range” under more flexible DGPs are presented in two recent papers by Christensen and Podolskij (2007) and Martens and van Dijk (2007).

11 When the DGP is specified to be log-normal or GARCH stochastic volatility diffusions, Patton and Sheppard (2009) find results very similar to those obtained for the case below. Using the same parameterisations as those in the simulations of Goncalves and Meddah (2009), slightly larger biases from the non-robust loss functions are found, but they generally differ from those in Table 2 only in the second decimal place. In contrast, the biases are found to be much larger under the two-factor stochastic volatility diffusion considered by Goncalves and Meddah (2009).
The range, or the high/low, estimator has been used in finance for many years, see Garman and Klass (1980) and Parkinson (1980). The intra-daily log range is defined as:

\[ R_G \equiv \max_t \log P_t - \min_r \log P_r, \quad t - 1 < r \leq t. \]  

(20)

Under the dynamics in Eq. (16) Feller (1951) presented the density of \( R_G \), and Parkinson (1980) presented a formula for obtaining moments of the range, which enable us to compute:

\[ E_{t-1}[R_G^2] = 4 \log (2) \cdot \sigma_t^2 \approx 2.7726 \sigma_t^2. \]  

(21)

Details on the distributional properties of the range under this DGP are presented in Patton (2006). The above expression shows that squared range is not a conditionally unbiased estimator of \( \sigma_t^2 \); we will thus focus below on the adjusted range:

\[ R_G^* = \frac{R_G}{2 \log (2)} \approx 0.6006 R_G. \]  

(22)

which, when squared, is an unbiased proxy for the conditional variance. Note that the adjustment factor depends critically on the assumed DGP, which is a potential drawback of the range as a volatility proxy. Using the results of Parkinson (1980) it is simple to determine that \( \text{MSE}_{t-1} [R_G^2] \approx 0.4073 \sigma_t^4 \), which is approximately one-fifth of the MSE of the daily squared range.

We now determine the optimal filters obtained using the various loss functions considered above, when \( \hat{\sigma}_t^2 = \text{RV}_t^{(m)} \) or \( \hat{\sigma}_t^2 = R_G^2 \) is used as a proxy for the conditional variance rather than \( \sigma_t^2 \). We initially leave \( m \) unspecified for the realised volatility proxy, and then specialise to three cases: \( m = 1, 13 \) and 78, corresponding to the use of daily, half-hourly and 5-min returns, on a stock listed on the New York Stock Exchange (NYSE).

For MSE and QLIKE the optimal filter is simply the conditional mean of \( \hat{\sigma}_t^2 \), which equals the conditional variance, as \( \text{RV}_t^{(m)} \) and \( R_G^2 \) are both conditionally unbiased. The MSE-SD loss function yields \( (E_{t-1} \{ \hat{\sigma}_t^2 \})^2 \) as the optimal forecast. Under the setup above,

\[ \text{RV}_t^{(m)} = \sum_{j=1}^m \hat{\sigma}_t^2, \quad \sigma_t^2 \equiv \frac{1}{m} \sum_{j=1}^m \hat{\sigma}_t^2 \]

so \( m \sigma_t^{-2} \text{RV}_t^{(m)} \sim \chi_m^2 \)

and

\[ \text{so } \hat{\sigma}_t^2 = \frac{1}{m} \left( E \left[ \sqrt{\chi_m^2} \right] \right)^2 \]

Notes: This table presents the forecast that minimises the conditional expected loss when the squared return is used as a volatility proxy. That is, \( h^* \) minimises \( E_{t-1}[L(\hat{\sigma}_t^2, h)] \) for various loss functions \( L \). The first column presents the solutions when returns have an arbitrary conditional distribution \( r_t | \mathcal{F}_{t-1} \sim F_t \) with mean zero and conditional variance \( \sigma_t^2 \), the second, third, and fourth columns present results with returns have a Student’s t distribution with mean zero, variance \( \sigma_t^2 \) and degrees of freedom \( v \), and the final column presents the solutions when returns are conditionally normally distributed. \( \Gamma \) is the gamma function and \( \Psi \) is the digamma function.

The expressions given for MAE-prop are based on a numerical approximation, see Patton (2006) for details.

### Notes

- The results for the MSE-SD loss function using realised volatility show that reducing the noise in the volatility proxy improves the optimal forecast, consistent with Hansen and Lunde (2006).
- Using the range we find that

\[ E \left[ \sqrt{\chi_m^2} \right] \approx \sqrt{m - \frac{1}{4 \sqrt{m}}} \]  

by a Taylor series approximation

so \( h_t^* \approx \alpha_t^2 \left( 1 - \frac{1}{2m} + \frac{1}{16m^2} \right) \)

\[ \approx 0.5625 \cdot \alpha_t^2 \]  

for \( m = 1 \)

\[ \approx 0.9619 \cdot \alpha_t^2 \]  

for \( m = 13 \)

\[ \approx 0.9936 \cdot \alpha_t^2 \]  

for \( m = 78 \).

The results for Table 2 confirm that as the proxy used to measure the true conditional variance gets more efficient the degree of distortion decreases for all loss functions. Using half-hour returns (13 intra-daily observations) or the intra-daily range still leaves substantial distortions in the optimal forecasts, but using 5-min returns (78 intra-daily observations) eliminates almost all of the bias, at least in this simple framework. While high frequency data is available and reliable for some assets (the most liquid assets on well-developed exchanges), for most assets it is not possible to obtain reliable high-frequency data, and thus the impact of noise in the volatility proxy cannot be ignored.

### 3. A class of robust loss functions

In the previous section we showed that amongst nine loss functions commonly used to compare volatility forecasts, only the MSE and the QLIKE loss functions lead to \( h_t^* = (E_{t-1} \{ \hat{\sigma}_t^2 \})^2 = \sigma_t^2 \), which is a necessary condition for a loss function to be robust

\[ \text{Note that the result for } m = 1 \text{ is different to that obtained in Section 2, which was } h_t^* = \frac{\hat{\sigma}_t^2}{v} \approx 0.6366 \sigma_t^2 \]. This is because for } m = 1 \text{ we can obtain the expression exactly, using results for the normal distribution, whereas for arbitrary } m \text{ we relied on a second-order Taylor series approximation.}
to noise in the volatility proxy. The following proposition is the main theoretical contribution of the paper; it provides a necessary and sufficient class of robust loss functions for volatility forecast comparison, which are related to the class of linear-exponential densities of Gourieroux et al. (1984), and to the work of Gourieroux et al. (1987). We will show below that this class contains an infinite number of loss functions, and allows for asymmetric penalties to be applied to over- versus under-predictions, as well as for a symmetric penalty. We make the following assumptions:

A1: $E_{t-1}[\hat{\sigma}_t^2] = \sigma_t^2$ for all $t$.

A2: $\hat{\sigma}_t^2 | F_{t-1} \sim F_t \in \bar{F}$, the set of all absolutely continuous distribution functions on $\mathbb{R}_+$.

A3: $L$ is twice continuously differentiable with respect to $h$ and $\sigma_t^2$, and has a unique minimum at $\hat{\sigma}_t^2 = h$.

A4: There exists some $h^*_t \in \text{int}(\mathcal{H})$ such that $h^*_t = E_{t-1}[\hat{\sigma}_t^2]$, where $\mathcal{H}$ is a compact subset of $\mathbb{R}_{++}$.

A5: $L$ and $F_t$ are such that: (a) $E_{t-1}[L(\hat{\sigma}_t^2, h)] < \infty$ for some $h \in \mathcal{H}$, (b) $|E_{t-1}[L(\hat{\sigma}_t^2, h)/\partial h]| \leq \infty$, and (c) $E_{t-1}[L(\hat{\sigma}_t^2, h)/\partial h^2] < \infty$, for all $t$.

**Proposition 2.** (i) The “MSE” loss function is the only robust loss function satisfying assumptions A1–A5 that depends solely on the forecast error, $\hat{\sigma}^2 - h$.

(ii) The “QLIKE” loss function is the only robust loss function satisfying assumptions A1–A5 that depends solely on the standardised forecast error, $\hat{\sigma}^2/h$.

The standardised forecast error will be centred approximately around 1 (if $h$ is somewhat accurate) and, more interestingly, the conditional variance of the standardised forecast error will be approximately 2 (under Gaussianity) regardless of the level of volatility of returns. Thus the average QLIKE loss will be less affected (generally) by the most extreme observations in the sample. The MSE loss, on the other hand, depends on the usual forecast error, $\hat{\sigma}^2 - h$, which will be centred approximately around zero, but will have variance that is proportional to the square of the variance of returns, i.e., $\sigma^4$. As noted by several previous authors, this implies that MSE is sensitive to extreme observations and the level of volatility of returns.

In most economic and financial applications, the choice of units of measurement is arbitrary, e.g., measuring prices in dollars versus cents, or measuring returns in percentages versus decimals. Given this, it is useful to consider the impact of a simple change in units on the ranking of two competing forecasts by expected loss. The class of loss functions presented in Proposition 1 guarantees that the true conditional variance will be chosen (subject to sampling variation) over any other forecast regardless of the choice units. However it does not guarantee that the ranking of two imperfect forecasts will be invariant to the choice of units. The following proposition shows that by using a homogeneous robust loss function, the ranking of any two (possibly imperfect) forecasts is invariant to a re-scaling of the data. It further provides an example where the ranking can be reversed simply with a re-scaling of the data if a non-homogeneous robust loss function is used.

**Proposition 3.** Recall that a loss function $L$ is homogeneous of order $k$ if

$$L(a \hat{\sigma}^2, ah) = a^k L(\hat{\sigma}^2, h) \quad \forall a > 0 \text{ for some } k.$$ 

Then:

(i) The ranking of any two (possibly imperfect) volatility forecasts by expected loss is invariant to a re-scaling of the data if the loss function is homogeneous.

</table>

Notes: This table presents the forecast that minimises the conditional expected loss when the range or realised volatility is used as a volatility proxy. That is, $\hat{h}_t^*$ minimises $E_{t-1}[L(\hat{\sigma}_t^2, h)]$, for $\hat{\sigma}_t^2 = RV_{t-1}$ or $\hat{\sigma}_t^2 = RV_t$, for various loss functions $L$. In all cases returns are assumed to be generated as a zero mean Brownian motion with constant volatility within each trading day and no jumps. The cases of $m = 1, 13, 78$ correspond to the use of daily squared returns, realised variance with 30-min returns and realised variance with 5-min returns respectively. The case that $m \to \infty$ corresponds to the case where the conditional variance is observable ex post without error.

$^{*}$ For the MSE-LOG and MAE-prop loss functions we used simulations, numerical integration and numerical optimisation to obtain the expressions given. Details on the computation of the figures in this table are given in Patton (2006).
The ranking of any two (possibly imperfect) volatility forecasts by expected loss may not be invariant to a re-scaling of the data if the loss function is robust but not homogeneous.

With the above motivation for homogeneous loss functions, we now derive the subset of homogeneous, robust loss functions. It turns out that this subset of functions is indexed by a single parameter, which determines the both degree of homogeneity and the shape of the loss function. Naturally, the MSE loss function is nested in this case (homogeneous of order 2), as is the QLIKE loss function (homogeneous of order zero).

**Proposition 4.** The following family of loss functions, indexed by the scalar parameter $b$, corresponds to the entire subset of robust and homogeneous loss functions. The degree of homogeneity is equal to $b + 2$.

$$
L(\hat{h}, h; b) = \begin{cases} 
1 & (b + 1)(b + 2)h^{b+2} \\
\sigma^2 - \hat{\sigma}^2 + \frac{\sigma^2}{h} - \frac{\sigma^2}{\hat{\sigma}^2} \frac{\log \hat{\sigma}^2}{h} & \text{for } b \not\in \{-1, -2\} \\
h - \frac{\sigma^2}{h} & \text{for } b = -1 \\
\frac{\hat{\sigma}^2}{h} - \frac{\sigma^2}{h} - 1 & \text{for } b = -2.
\end{cases}
$$

(24)

The MSE loss function is obtained when $b = 0$ and the QLIKE loss function is obtained when $b = -2$, up to additive and multiplicative constants. In Fig. 1 we present the above class of functions for various values of $b$, ranging from $1$ to $-5$, and including the MSE and QLIKE cases. This figure shows that this family of loss functions can take a wide variety of shapes, ranging from symmetric ($b = 0$, corresponding to MSE) to asymmetric, with heavier penalty either on under-prediction ($b < 0$) or over-prediction ($b > 0$). Fig. 2 plots the ratio of losses incurred for negative forecast errors to those incurred for positive forecast errors, to make clearer the form of asymmetries in these loss functions. Other considerations when choosing a loss function from the class in Eq. (24) include the moment conditions required for formal tests and the finite-sample power of these tests. Patton (2006) presents results on how moment and memory conditions required for DMW tests vary with the shape parameter $b$. It is noteworthy that the moment conditions required under MSE loss are substantially stronger than those using QLIKE loss. Related to this, Patton and Sheppard (2009) find that the power of DMW tests using QLIKE loss are higher than those using MSE loss, providing further motivation for using QLIKE rather than MSE in volatility forecasting applications.

4. Empirical application to forecasting IBM return volatility

In this section we consider the problem of forecasting the conditional variance of the daily open-to-close return on IBM, using data from the TAQ database over the period from January 1993 to December 2003. We consider two simple volatility forecasting models that are widely used in industry: a 60-day rolling window forecast, and the RiskMetrics volatility forecast based on daily returns:

Rolling window: $h_{1t} = \frac{1}{60} \sum_{j=1}^{60} r_{t-j}^2$ \hspace{1cm} (25)

RiskMetrics: $h_{2t} = \lambda h_{2t-1} + (1 - \lambda) r_{t-1}^2, \hspace{1cm} \lambda = 0.94.$ \hspace{1cm} (26)

We use approximately the first year of observations (272 observations) to initialise the RiskMetrics forecasts, and the remaining 2500 observations to compare the forecasts. A plot of the volatility forecasts is provided in Fig. 3. Recall that the theory in the previous section requires that the volatility proxy ($\hat{\sigma}^2$) is conditionally unbiased, but no such assumption is required for the volatility forecasts ($h_t$): the rolling window and RiskMetrics forecasts can be biased, or inaccurate in other ways. (Indeed, Mincer–Zarnowitz tests reported in Patton (2006) indicate that both of these forecasts are biased.)

We employ a variety of volatility proxies in the comparison of these forecasts: the daily squared return, and realised variance (RV) computed using 65-min, 15-min and 5-min returns.\(^{13}\) In order for the theory in the previous section to be applied, we require the proxy to be conditionally unbiased. For a liquid stock such as IBM, all of these proxies can plausibly be considered free from market microstructure effects. The same is not likely true for very high

\(^{13}\) We use 65-min returns rather than 60-min returns so that there are an even number of intervals within the NYSE trade day, which runs from 9:30 am to 4 pm.
Comparison of rolling window and RiskMetrics forecasts, January 1994 to December 2003.

Notes: This table presents the \( t \)-statistics from Diebold–Mariano–West tests of equal predictive accuracy for a 60-day rolling window forecast and a RiskMetrics forecast, for IBM over the period January 1994 to December 2003. A \( t \)-statistic greater than 1.96 in absolute value indicates a rejection of the null of equal predictive accuracy at the 0.05 level. These statistics are marked with an asterisk. The sign of the \( t \)-statistics indicates which forecast performed better for each loss function: a positive \( t \)-statistic indicates that the rolling window forecast produced larger average loss than the RiskMetrics forecast, while a negative sign indicates the opposite.

Fig. 3. Conditional variance forecasts for IBM returns from 60-day rolling window and RiskMetrics models, January 1994 to December 2003.
Appendix

Proof of Proposition 1. We prove this proposition by showing the equivalence of the following three statements:

1: The loss function takes the form given the statement of the proposition;

2: The loss function is robust in the sense of Definition 1;

3: The optimal forecast under the loss function is the conditional variance.

We will show that $1 \Rightarrow 2 \Rightarrow 3 \Rightarrow 1$. That $1 \Rightarrow 2$ follows from Hansen and Lunde (2006); their assumption 2 is satisfied given the assumptions for the proposition and noting that $T(\hat{\sigma}^2, h)/T(\hat{\sigma}^2) = T(\hat{\sigma}^2, h)$ does not depend on $h$.

We next show that $2 \Rightarrow 3$: by the definition of $h_1$ we have

$$E_{t-1} \left[ L(\hat{\sigma}^2, h_1) \right] \leq E_{t-1} \left[ L(\hat{\sigma}^2, \tilde{h}_t) \right]$$

for any other sequence of $\tilde{F}_{t-1}$-measurable forecasts $\tilde{h}_t$. Then

$$E \left[ L(\hat{\sigma}^2, h_1) \right] \leq E \left[ L(\hat{\sigma}^2, \tilde{h}_t) \right]$$

by the LIE and

$$E \left[ L(\hat{\sigma}^2, h_1) \right] \leq E \left[ L(\hat{\sigma}^2, \tilde{h}_t) \right]$$

since $L$ is robust under $2$.

But $L(\hat{\sigma}^2, h)$ has a unique minimum at $\hat{\sigma}^2 = h$, and if we set $h_1 = \alpha^2$ then it must be the case that $h_1 = \alpha^2$.

Proving $3 \Rightarrow 1$ is more challenging. For this part we follow the proof of Theorem 1 of Komunjer and Vuong (2006), adapted to our problem. We seek to show that the functional form of the loss function given in the proposition is necessary for $h_1 = E_{t-1}[\hat{\alpha}^2]$, for any $\tilde{F}_t \in \tilde{F}$. Notice that we can write

$$\frac{\partial L(\hat{\sigma}^2, h_1)}{\partial h} = c(\hat{\sigma}^2, h_1)(\hat{\alpha}^2 - h_1)$$

where $c(\hat{\sigma}^2, h_1)$ is $c(\hat{\sigma}^2 - h_1)^{-1}\partial L(\hat{\sigma}^2, h_1)/\partial h$, since $\hat{\sigma}^2 \neq h_1$, a.s. by assumption A2. Now decompose $c(\hat{\sigma}^2, h_1)$ into

$$c(\hat{\sigma}^2, h_1) = E_{t-1}[c(\hat{\sigma}^2, h_1)] + \varepsilon_t$$

where $E_{t-1}[\varepsilon_t] = 0$. Thus

$$E_{t-1}\left[ \frac{\partial L(\hat{\sigma}^2, h_1)}{\partial h} \right] = E_{t-1}\left[ c(\hat{\sigma}^2, h_1)(\hat{\alpha}^2 - h_1) \right]$$

$$= E_{t-1}\left[ c(\hat{\sigma}^2, h_1) \right] E_{t-1}[\hat{\alpha}^2 - h_1] + E_{t-1}[\varepsilon_t(\hat{\alpha}^2 - h_1)].$$

If $E_{t-1}[\partial L(\hat{\sigma}^2, h_1)/\partial h] = 0$ for $h_1 = E_{t-1}[\hat{\sigma}^2]$, then it must be that $E_{t-1}[\hat{\alpha}^2 - h_1] = 0 \Rightarrow E_{t-1}[\hat{\alpha}^2 - h_1] = 0$ for all $F_t \in \tilde{F}$. Employing a generalised Farkas lemma, see Lemma 8.1 of Gourieroux and Monfort (1996), this implies that $\lambda \in \mathbb{R}$ such that $\lambda (\hat{\alpha}^2 - h_1) = \varepsilon_t(\hat{\sigma}^2 - h_1)$ for every $F_t \in \tilde{F}$ and all $t$. Since $\hat{\alpha}^2 - h_1 \neq 0$ a.s. by assumption A2 this implies that $\varepsilon_t = \lambda$ a.s. for all $t$. Since $E_{t-1}[\varepsilon_t] = 0$ we then have $\lambda = 0$. Thus $c(\hat{\sigma}^2, h_1) = E_{t-1}[c(\hat{\sigma}^2, h_1)]$ for all $t$, which implies that $c(\hat{\sigma}^2, h_1) = c(h_1)$, and thus that $\partial L(\hat{\sigma}^2, h_1)/\partial h = c(h_1)(\hat{\alpha}^2 - h_1)$.

The remainder of the proof is straightforward: A necessary condition for $h_1$ to minimise $E_{t-1}[L(\hat{\sigma}^2, h)]$ is that $E_{t-1}[\partial^2 L(\hat{\sigma}^2, h_1)/\partial h^2] \geq 0$, using A5 to interchange expectation and differentiation. Using the previous result we have:

$$E_{t-1}\left[ \frac{\partial^2 L(\hat{\sigma}^2, h_1)}{\partial h^2} \right] = E_{t-1}\left[ c(\hat{\alpha}^2 - h_1) - c(h_1) \right]$$

$$= -c(h_1)$$

which is non-negative ifc $c(h_1)$ is non-positive. From assumption A4 we know that the optimum is in the interior of $\mathcal{H}$ and so we know that $c \neq 0$, and thus $c(h) < 0 \forall h \in \mathcal{H}$. To obtain the loss function corresponding to the given first derivative we simply integrate up:

$$L(\hat{\sigma}^2, h) =\hat{\sigma}^2 \int (c(h) dh) - \int c(h) h dh$$

$$= B(\hat{\sigma}^2) + \hat{\sigma}^2 C(h) - C(h) h + \int C(h) dh$$

$$= \tilde{C}(h) + B(\hat{\sigma}^2) + C(h)(\hat{\sigma}^2 - h)$$

where $C$ is a strictly decreasing function (i.e. $C^2 \equiv c$ is negative) and $\tilde{C}$ is the anti-derivative of $C$. By assumption A3 both $B$ and $C$ are twice continuously differentiable. Thus $3 \Rightarrow 1$, completing the proof. □

Proof of Proposition 2. Without loss of generality, we work below with loss functions that have been normalised to imply zero loss when the forecast error is zero: $L(\hat{\sigma}^2, h) = \tilde{C}(h) - \tilde{C}(\hat{\sigma}^2) + C(h)(\hat{\sigma}^2 - h)$.

(i) We want to find the general sub-set of loss functions that satisfy $L(\hat{\sigma}^2, h) \equiv L(\hat{\sigma}^2 - h)$ for some function $\tilde{L}$. This condition implies

$$\frac{\partial L(\hat{\sigma}^2, h)}{\partial \hat{\sigma}^2} = -\frac{\partial L(\hat{\sigma}^2, h)}{\partial h} \forall (\hat{\sigma}^2, h)$$

$$-C(\hat{\sigma}^2) + C(h) + C'(h)(\hat{\sigma}^2 - h) = 0 \forall (\hat{\sigma}^2, h).$$

Taking the derivative of both sides w.r.t. $\hat{\sigma}^2$ we obtain:

$$-C'(\hat{\sigma}^2) + C'(h) = 0 \forall (\hat{\sigma}^2, h)$$

which implies $C'(h) = \kappa_1 h$ a.s. and since we know $C$ is strictly decreasing, we also have $\kappa_1 < 0$.

so $C(h) = \kappa_1 h + \kappa_2 (\hat{\sigma}^2)$

and

$$\tilde{C}(h) = \frac{1}{2}\kappa_1 h^2 + \kappa_2 (\hat{\sigma}^2) h + \kappa_3 (\hat{\sigma}^2)$$

where $\kappa_2, \kappa_3$ are constants of integration, and may be functions of $\hat{\sigma}^2$. Thus the loss function becomes

$$L(\hat{\sigma}^2, h) = \frac{1}{2}\kappa_1 h^2 + \kappa_2 (\hat{\sigma}^2) h + \kappa_3 (\hat{\sigma}^2) \frac{1}{2} \kappa_1 \hat{\sigma}^4 - \kappa_2 (\hat{\sigma}^2) \hat{\sigma}^2 - \kappa_3 (\hat{\sigma}^2) + (\kappa_1 h + \kappa_2 (\hat{\sigma}^2))(\hat{\sigma}^2 - h)$$

$$= -\frac{1}{2}\kappa_1 (\hat{\sigma}^2 - h)^2.$$
Using Proposition 4 below, this implies that the loss function must be of the form:

\[
L(\hat{\delta}^2, h) = \frac{\hat{\delta}^2}{h} - \log \frac{\hat{\delta}^2}{h} - 1
\]

which is the LIQUE loss function up to additive and multiplicative constants.

**Proof of Proposition 3.** (i) If \( L \) is homogeneous then \( E[L(a\hat{\delta}^2, ah)] \geq E[L(\hat{\delta}^2, h)] \geq E[a^2L(\hat{\delta}^2, h)] \)

\( \iff \)

\( E[L(\hat{\delta}^2, h)] \geq E[L(\hat{\delta}^2, h)] \), for any \( a > 0 \).

(ii) Here we need only provide an example. Consider the following stylised case: \( \sigma^2_x = 1 \) a.s. \( \forall t \), \( \langle h_{11}, h_{22} \rangle = (\gamma_1, \gamma_2) \) \( \forall t \), and \( \hat{\delta}^2 \) is such that \( E_\pi(\hat{\delta}^2) = 1 \) a.s. \( \forall t \). As a robust but non-homogeneous loss we will use the one generated by the following specification for \( C^* \):

\[
C^*(h) = -\log (1+h)
\]

so \( C(h) = h - (1+h) \log (1+h) \)

and \( \bar{C}(h) = \frac{1}{4} \left[ h(3h+2) - 2(1+h)^2 \log (1+h) \right] \).

For small \( h \) this loss function resembles the \( b = 1 \) loss function from Proposition 4 (up to a scaling constant), but for medium to large \( h \) this loss function does not correspond to any in Proposition 4.

Given this set-up, we have

\[
E \left[ L(a\hat{\delta}^2, ah) \right] = \frac{1}{4} \left[ a^2 \gamma_1 (3a\gamma_2 + 2) - 2(1+a\gamma_1)^2 \log (1+a\gamma_1) \right] - E \left[ \bar{C}(a\hat{\delta}^2) \right] + a \left[ \gamma_1 (1 + a\gamma_1) \log (1+a\gamma_1) \right] \left( 1 - \gamma_1 \right) .
\]

Then define

\[
d_i(\gamma_1, \gamma_2, a) = \frac{L(a\hat{\delta}^2, a\hat{\gamma}_1) - L(\hat{\delta}^2, \hat{\gamma}_1) \gamma_1}{4}.
\]

\[
E \left[ d_i(\gamma_1, \gamma_2, a) \right] = \frac{a}{4} \left( \gamma_1 - \gamma_2 \right) \left( 2 - 4a - a \left( \gamma_1 + \gamma_2 \right) \right)
\]

\[
+ \frac{1}{2} \left( a^2 \left( \gamma_1 - 1 \right)^2 - (1+a)^2 \right) \log (1+a\gamma_1)
\]

\[
- \frac{1}{2} \left( a^2 \left( \gamma_2 - 1 \right)^2 - (1+a)^2 \right) \log (1+a\gamma_2) .
\]

Let \( h_{11} = \gamma_1 = 1/3 \) and let \( h_{22} = \gamma_2 = 3/2 \). Then \( E[d_i(h_{11}, h_{22}, 1)] = -0.0087 \), and so the first forecast has lower expected loss than the second using the "original" scaling of the data, but \( E[d_i(h_{11}, h_{22}, 2)] = 0.0691 \), and so if all variables are multiplied by 2 then the second forecast has lower expected loss than the first.

**Proof of Proposition 4.** We seek the subset of robust loss functions that are homogeneous of order \( k \): \( L(a\hat{\delta}^2, ah) = a^kL(\hat{\delta}^2, h) \) \( \forall a > 0 \). Let

\[
\lambda(\hat{\delta}^2, h) = aL(\hat{\delta}^2, h)/h
\]

\[= C^*(h)(\hat{\delta}^2 - h) \] for robust loss functions.

Since \( L \) is homogeneous of order \( k \), \( \lambda \) is homogeneous of order \( (k-1) \). This implies \( \lambda(a\hat{\delta}^2, ah) = a^{k-1}\lambda(\hat{\delta}^2, h) = a^{k-1}C^*(h)(\hat{\delta}^2 - h) \), while direct substitution yields \( \lambda(a\hat{\delta}^2, ah) = aC^*(ah)(\hat{\delta}^2 - h) \). Thus \( C^*(ah) = a^{k-1}C^*(h) \) \( \forall a > 0 \), that is, \( C^* \) is homogeneous of order \( (k-2) \).

Next we apply Euler’s Theorem to \( C^* \): \( C^*(h)h = (k - 2)C^*(h)h \) \( \forall h > 0 \), and so

\[(k - 2)C^*(h) + C^*(h)h = 0.\]

We can solve this first-order differential equation to find:

\[
C^*(h) = \gamma h^{k-2}
\]

where \( \gamma \) is an unknown scalar. Since \( C^* < 0 \) we know that \( \gamma < 0 \), and as this is just a scaling parameter we set it to \( -1 \) without loss of generality.

\[
C^*(h) = -h^{k-2}
\]

\[
\bar{C}(h) = \left\{ \begin{array}{ll}
\frac{1}{1-k} & k \neq 1 \\
-\log h + z_1 & k = 1
\end{array} \right.
\]

where \( z_1 \) and \( z_2 \) are constants of integration. Finally, we substitute the expressions for \( C \) and \( \bar{C} \) into Eq. \((23)\), set \( \beta = -C \), and simplify to obtain the loss functions in Eq. \((24)\) with \( k = b + 2 \).
