1. Introduction

A number of economists have wanted to measure downside risk, the risk of prices falling, just using information based on negative returns – a prominent recent example is by Ang, Chen, and Xing (2006). This has been operationalized by quantities such as semivariance, value at risk and expected shortfall, which are typically estimated using daily returns. In this chapter we introduce a new measure of the variation of asset prices based on high frequency data. It is called realized semivariance (RS). We derive its limiting properties, relating it to quadratic variation and, in particular, negative jumps. Further, we show it has some useful properties in empirical work, enriching the standard ARCH models.
Measuring downside risk – realized semivariance

Pioneered by Rob Engle over the last 25 years and building on the recent econometric literature on realized volatility.

Realized semivariance extends the influential work of, for example, Andersen, Bollerslev, Diebold, and Labys (2001) and Barndorff-Nielsen and Shephard (2002), on formalizing so-called realized variances (RV), which links these commonly used statistics to the quadratic variation process. Realized semivariance measures the variation of asset price falls. At a technical level it can be regarded as a continuation of the work of Barndorff-Nielsen and Shephard (2004) and Barndorff-Nielsen and Shephard (2006), who showed it is possible to go inside the quadratic variation process and separate out components of the variation of prices into that due to jumps and that due to the continuous evolution. This work has prompted papers by, for example, Andersen, Bollerslev, and Diebold (2007), Huang and Tauchen (2005) and Lee and Mykland (2008) on the importance of this decomposition empirically in economics. Surveys of this kind of thinking are provided by Andersen, Bollerslev, and Diebold (2007) and Barndorff-Nielsen and Shephard (2007), while a detailed discussion of the relevant probability theory is given in Jacod (2007).

Let us start with statistics and results which are well known. Realized variance estimates the ex post variance of log asset prices \( Y \) over a fixed time period. We will suppose that this period is 0 to 1. In our applied work it can be thought of as any individual day of interest. Then RV is defined as

\[
RV = \sum_{j=1}^{n} (Y_{t_j} - Y_{t_{j-1}})^2
\]

where \( 0 = t_0 < t_1 < \ldots < t_n = 1 \) are the times at which (trade or quote) prices are available. For arbitrage free-markets, \( Y \) must follow a semimartingale. This estimator converges as we have more and more data in that interval to the quadratic variation at time one,

\[
[Y]_1 = p - \lim_{n \to \infty} \sum_{j=1}^{n} (Y_{t_j} - Y_{t_{j-1}})^2,
\]

(e.g. Protter, 2004, pp. 66–77) for any sequence of deterministic partitions \( 0 = t_0 < t_1 < \ldots < t_n = 1 \) with \( \sup_j \{t_{j+1} - t_j\} \to 0 \) for \( n \to \infty \). This limiting operation is often referred to as “in-fill asymptotics” in statistics and econometrics.\(^\dagger\)

One of the initially strange things about realized variance is that it solely uses squares of the data, whereas the research of, for example, Black (1976), Nelson (1991), Glosten, Jagannathan, and Runkle (1993) and Engle and Ng (1993) has indicated the importance of falls in prices as a driver of conditional variance. The reason for this is clear, as the high-frequency data become dense, the extra information in the sign of the data can fall to zero for some models – see also the work of Nelson (1992). The most elegant framework

\(^\dagger\)When there are market frictions it is possible to correct this statistic for their effect using the two-scale estimator of Zhang, Mykland, and Aitm-Sahalia (2005), the realized kernel of Barndorff-Nielsen, Hansen, Lunde, and Shephard (2008) or the pre-averaging based statistic of Jacod, Li, Mykland, Podolskij, and Vetter (2007).
in which to see this is where $Y$ is a Brownian semimartingale

$$Y_t = \int_0^t a_s \, ds + \int_0^t \sigma_s \, dW_s, \quad t \geq 0,$$

where $a$ is a locally bounded predictable drift process and $\sigma$ is a càdlàg volatility process – all adapted to some common filtration $\mathcal{F}_t$, implying the model can allow for classic leverage effects. For such a process

$$[Y]_t = \int_0^t \sigma^2_s \, ds,$$

and so

$$d[Y]_t = \sigma^2_t \, dt,$$

which means for a Brownian semimartingale the quadratic variation (QV) process tells us everything we can know about the ex post variation of $Y$ and so $RV$ is a highly interesting statistic. The signs of the returns are irrelevant in the limit – this is true whether there is leverage or not.

If there are jumps in the process there are additional things to learn than just the QV process. Let

$$Y_t = \int_0^t a_s \, ds + \int_0^t \sigma_s \, dW_s + J_t,$$

where $J$ is a pure jump process. Then, writing jumps in $Y$ as $\Delta Y_t = Y_t - Y_{t-}$,

$$[Y]_t = \int_0^t \sigma^2_s \, ds + \sum_{s \leq t} (\Delta Y_s)^2,$$

and so QV aggregates two sources of risk. Even when we employ bipower variation (Barndorff-Nielsen and Shephard, 2004 and Barndorff-Nielsen and Shephard, 2006$^2$), which allows us to estimate $\int_0^t \sigma^2_s \, ds$ robustly to jumps, this still leaves us with estimates of $\sum_{s \leq t} (\Delta J_s)^2$. This tells us nothing about the asymmetric behavior of the jumps – which is important if we wish to understand downside risk.

In this chapter we introduce the downside realized semivariance ($RS^-$)

$$RS^- = \sum_{j=1}^{t \leq 1} (Y_{t_j} - Y_{t_{j-1}})^2 1_{Y_{t_j} - Y_{t_{j-1}} \leq 0},$$

where $1_y$ is the indicator function taking the value 1 if the argument $y$ is true. We will study the behavior of this statistic under in-fill asymptotics. In particular we will see that

$$RS^- \overset{p}{\rightarrow} \frac{1}{2} \int_0^1 \sigma_s^2 \, ds + \sum_{s \leq 1} (\Delta Y_s)^2 1_{\Delta Y_s \leq 0}.$$ 

$^2$Threshold-based decompositions have also been suggested in the literature, examples of this include Mancini (2001), Jacod (2007) and Lee and Mykland (2008).
Measuring downside risk – realized semivariance

under in-fill asymptotics. Hence $RS^-$ provides a new source of information, one which focuses on squared negative jumps.\footnote{This type of statistic relates to the work of Balsiria and Zakoian (2001) who built separate ARCH-type conditional variance models of daily returns using positive and negative daily returns. It also resonates with the empirical results in a recent paper by Chen and Ghysels (2007) on news impact curves estimated through semiparametric MIDAS regressions.} Of course the corresponding upside realized semivariance

$$RS^+ = \sum_{j=1}^{t_j \leq 1} (Y_{t_j} - Y_{t_j-1})^2 1_{Y_{t_j} - Y_{t_j-1} \geq 0}$$

may be of particular interest to investors who have short positions in the market (hence a fall in price can lead to a positive return and hence is desirable), such as hedge funds. Of course,

$$RV = RS^- + RS^+.$$  

Semivariances, or more generally measures of variation below a threshold (target semivariance) have a long history in finance. The first references are probably Markowitz (1959), Mao (1970b), Mao (1970a), Hogan and Warren (1972) and Hogan and Warren (1974). Examples include the work of Fishburn (1977) and Lewis (1990). Sortino ratios (which are an extension of Sharpe ratios and were introduced by Sortino and van der Meer, 1991), and the so-called post-modern portfolio theory by, for example, Rom and Ferguson (1993), has attracted attention. Sortino and Satchell (2001) look at recent developments and provide a review, whereas Pedersen and Satchell (2002) look at the economic theory of this measure of risk. Our innovation is to bring high-frequency analysis to bear on this measure of risk.

The empirical essence of daily downside realized semivariance can be gleaned from Figure 7.1, which shows an analysis of trades on General Electric (GE) carried out on the New York Stock Exchange\footnote{These data are taken from the TAQ database, managed through WRDS. Although information on trades is available from all the different exchanges in the US, we solely study trades which are made at the exchange in New York.} from 1995 to 2005 (giving us 2,616 days of data). In graph (a) we show the path of the trades drawn in trading time on a particular randomly chosen day in 2004, to illustrate the amount of daily trading which is going on in this asset. Notice by 2004 the tick size has fallen to one cent.

Graph (b) shows the open to close returns, measured on the log-scale and multiplied by 100, which indicates some moderation in the volatility during the last and first piece of the sample period. The corresponding daily realized volatility (the square root of the realized variance) is plotted in graph (c), based upon returns calculated every 15 trades. The Andersen, Bollerslev, Diebold, and Labys (2000) variance signature plot is shown in graph (d), to assess the impact of noise on the calculation of realized volatility. It suggests statistics computed on returns calculated every 15 trades should not be too sensitive to noise for GE. Graph (e) shows the same but focusing on daily $RS^-$ and $RS^+$. Throughout, the statistics are computed using returns calculated every 15 trades.
1 Introduction

Fig. 7.1. Analysis of trades on General Electric carried out on the NYSE from 1995 to 2005. (a) Path of the trades drawn in trading time on a random day in 2004. (b) Daily open to close returns $r_i$, measured on the log-scale and multiplied by 100. The corresponding daily realized volatility ($\sqrt{RV_i}$) is plotted in graph (c), based upon returns calculated every 15 trades. (d) Variance signature plot in trade time to assess the impact of noise on the calculation of realized variance ($RV_i$). (e) Same thing, but for the realized semivariances ($RS_i^+$ and $RS_i^-$). (f) Correlogram for $RS_i^+$, $RV_i$ and $RS_i^-$. It indicates they are pretty close to one another on average over this sample period. This component signature plot is in the spirit of the analysis pioneered by Andersen, Bollerslev, Diebold, and Labys (2001) in their analysis of realized variance. Graph (f) shows the correlogram for the downside realized semivariance and the realized variance and suggests the downside realized semivariance has much more dependence in it than $RS^+$. Some summary statistics for these data are available in Table 7.2, which will be discussed in some detail in Section 3.

In the realized volatility literature, authors have typically worked out the impact of using realized volatilities on volatility forecasting using regressions of future realized variance on lagged realized variance and various other explanatory variables.\(^5\) Engle and Gallo (2006) prefer a different route, which is to add lagged realized quantities as variance regressors in Engle (2002) and Bollerslev (1986) GARCH-type models of daily

\(^5\)Leading references include Andersen, Bollerslev, Diebold, and Labys (2001) and Andersen, Bollerslev, and Meddah (2004).
returns—the reason for their preference is that it is aimed at a key quantity, a predictive model of future returns, and is more robust to the heteroskedasticity inherent in the data. Typically when Engle generalizes to allow for leverage he uses the Glosten, Jagannathan, and Runkle (1993) (GJR) extension. This is the method we follow here. Throughout we will use the subscript \( i \) to denote discrete time.

We model daily open to close returns \( \{ r_i; i = 1, 2, \ldots, T \} \) as
\[
E(r_i|G_{i-1}) = \mu, \\
\begin{align*}
\sigma_i^2 &= \text{Var}(r_i|G_{i-1}) = \omega + \alpha (r_{i-1} - \mu)^2 + \beta \sigma_{i-1}^2 \\
 &\quad + \delta (r_{i-1} - \mu)^2 I_{r_{i-1} - \mu < 0} + \gamma' z_{i-1},
\end{align*}
\]
and then use a standard Gaussian quasi-likelihood to make inference on the parameters, e.g., Bollerslev and Wooldridge (1992). Here \( z_{i-1} \) are the lagged daily realized regressors and \( G_{i-1} \) is the information set generated by discrete time daily statistics available to forecast \( r_i \) at time \( i - 1 \).

Table 7.1 shows the fit of the GE trade data from 1995 to 2005. It indicates the lagged \( RS^- \) beating out of the GARCH model (\( \delta = 0 \)) and the lagged RV. Both realized terms yield large likelihood improvements over a standard daily returns-based GARCH. Importantly there is a vast shortening in the information-gathering period needed to condition on, with the GARCH memory parameter \( \beta \) dropping from 0.953 to around 0.7. This makes fitting these realized-based models much easier in practice, allowing their use on relatively short time series of data.

When the comparison with the GJR model is made, which allows for traditional leverage effects, the results are more subtle, with the \( RS^- \) significantly reducing the importance of the traditional leverage effect while the high-frequency data still has an important impact on improving the fit of the model. In this case the \( RS^- \) and RV play similar roles, with \( RS^- \) no longer dominating the impact of the RV in the model.

The rest of this chapter has the following structure. In Section 2 we will discuss the theory of realized semivariances, deriving a central limit theory under some mild assumptions. In Section 3 we will deepen the empirical work reported here, looking at a variety of stocks and also both trade and quote data. In Section 4 we will discuss various extensions and areas of possible future work.

## 2. Econometric theory

### 2.1. The model and background

We start this section by repeating some of the theoretical story from Section 1.

---

6We have no high frequency data to try to estimate the variation of the prices over night and so do not attempt to do this here. Of course, it would be possible to build a joint model of open to close and close to open returns, conditional on the past daily data and the high frequency realised terms but we have not carried this out here. An alternative would be to model open to open or close to close prices given past data of the same type and the realised quantities. This is quite a standard technique in the literature, but not one we follow here.

Gaussian quasi-likelihood fit of GARCH and GJR models fitted to daily open to close returns on General Electric share prices, from 1995 to 2005. We allow lagged daily realized variance (RV) and realized semivariance (RS) to appear in the conditional variance. They are computed using every 15th trade. T-statistics, based on robust standard errors, are reported in small font and in brackets.
Measuring downside risk – realized semivariance

Consider a Brownian semimartingale $Y$ given as

$$Y_t = \int_0^t a_s ds + \int_0^t \sigma_s dW_s,$$  \hspace{1cm} (1)

where $a$ is a locally bounded predictable drift process and $\sigma$ is a càdlàg volatility process. For such a process

$$[Y]_t = \int_0^t \sigma_s^2 ds,$$

and so $d[Y]_t = \sigma_t^2 dt$, which means that when there are no jumps the QV process tells us everything we can know about the \textit{ex post} variation of $Y$.

When there are jumps this is no longer true, in particular let

$$Y_t = \int_0^t a_s ds + \int_0^t \sigma_s dW_s + J_t,$$  \hspace{1cm} (2)

where $J$ is a pure jump process. Then

$$[Y]_t = \int_0^t \sigma_s^2 ds + \sum_{s \leq t} (\Delta J_s)^2,$$

and $d[Y]_t = \sigma_t^2 dt + (\Delta Y_t)^2$. Even when we employ devices like realized bipower variation (Barndorff-Nielsen and Shephard, 2004 and Barndorff-Nielsen and Shephard, 2006)

$$BPV = \mu_1^{-2} \sum_{j=2}^{t \leq} \left| Y_{t_j} - Y_{t_{j-1}} \right| \left| Y_{t_{j-1}} - Y_{t_{j-2}} \right| \overset{P}{\to} \{Y\}_t^{[1,1]} = \int_0^t \sigma_s^2 ds,$$

$$\mu_1 = E|U|, \quad U \sim N(0,1),$$

we are able to estimate $\int_0^t \sigma_s^2 ds$ robustly to jumps, but this still leaves us with estimates of $\sum_{s \leq t} (\Delta J_s)^2$. This tells us nothing about the asymmetric behavior of the jumps.

2.2. Realized semivariances

The empirical analysis we carry out throughout this chapter is based in trading time, so data arrive into our database at irregular points in time. However, these irregularly spaced observations can be thought of as being equally spaced observations on a new time-changed process, in the same stochastic class, as argued by, for example, Barndorff-Nielsen, Hansen, Lunde, and Shephard (2008). Thus there is no loss in initially considering equally spaced returns

$$y_i = Y_{\frac{i}{n}} - Y_{\frac{i-1}{n}}, \quad i = 1, 2, \ldots, n.$$

We study the functional

$$V(Y, n) = \sum_{i=1}^{[nt]} \left( \frac{y_i^2 1_{\{y_i \geq 0\}}}{y_i^2 1_{\{y_i \leq 0\}}} \right).$$  \hspace{1cm} (3)
2 Econometric theory

The main results then come from an application of some limit theory of Kinnebrock and Podolskij (2008) for bipower variation. This work can be seen as an important generalization of Barndorff-Nielsen, Graversen, Jacod, and Shephard (2006) who studied bipower-type statistics of the form

$$\frac{1}{n} \sum_{i=2}^{n} g(\sqrt{n}y_i)h(\sqrt{n}y_{i-1}),$$

when g and h were assumed to be even functions. Kinnebrock and Podolskij (2008) give the extension to the uneven case, which is essential here.

**Proposition 1** Suppose (1) holds, then

$$\sum_{i=1}^{\lfloor nt \rfloor} \left(\frac{y_{i1}^{2}1_{\{y_{i} \geq 0\}}}{y_{i1}^{2}1_{\{y_{i} \leq 0\}}} \right) \overset{p}{\longrightarrow} \frac{1}{2} \int_{0}^{t} \sigma_{s}^{2}ds \left(\begin{array}{c} 1 \\ 1 \end{array}\right).$$

**Proof** Trivial application of Theorem 1 in Kinnebrock and Podolskij (2008).

**Corollary 1** Suppose

$$Y_t = \int_{0}^{t} a_s ds + \int_{0}^{t} \sigma_s dW_s + J_t,$$

holds, where J is a finite activity jump process then

$$\sum_{i=1}^{\lfloor nt \rfloor} \left(\frac{y_{i1}^{2}1_{\{y_{i} \geq 0\}}}{y_{i1}^{2}1_{\{y_{i} \leq 0\}}} \right) \overset{p}{\longrightarrow} \sum_{s \leq t} \left(\frac{(\Delta Y_s)^{2}1_{\{\Delta Y_s \geq 0\}}}{(\Delta Y_s)^{2}1_{\{\Delta Y_s \leq 0\}}} \right).$$

**Remark 1** The above means that

$$(1, -1) \sum_{i=1}^{\lfloor nt \rfloor} \left(\frac{y_{i1}^{2}1_{\{y_{i} \geq 0\}}}{y_{i1}^{2}1_{\{y_{i} \leq 0\}}} \right) \overset{p}{\longrightarrow} \sum_{s \leq t} \left(\frac{(\Delta Y_s)^{2}1_{\{\Delta Y_s \geq 0\}}}{(\Delta Y_s)^{2}1_{\{\Delta Y_s \leq 0\}}} - (\Delta Y_s)^{2}1_{\{\Delta Y_s \leq 0\}} \right),$$

the difference in the squared jumps. Hence this statistic allows us direct econometric evidence on the importance of the sign of jumps. Of course, by combining with bipower variation

$$\sum_{i=1}^{\lfloor nt \rfloor} \left(\frac{y_{i1}^{2}1_{\{y_{i} \geq 0\}}}{y_{i1}^{2}1_{\{y_{i} \leq 0\}}} \right) - \frac{1}{2} \left(\frac{BPV}{BPV}\right) \overset{p}{\longrightarrow} \sum_{s \leq t} \left(\frac{(\Delta Y_s)^{2}1_{\{\Delta Y_s \geq 0\}}}{(\Delta Y_s)^{2}1_{\{\Delta Y_s \leq 0\}}} \right),$$

we can straightforwardly estimate the QV of just positive or negative jumps.

In order to derive a central limit theory we need to make two assumptions on the volatility process.

**H1** If there were no jumps in the volatility then it would be sufficient to employ

$$\sigma_t = \sigma_0 + \int_{0}^{t} a_s ds + \int_{0}^{t} \sigma_s dW_s + \int_{0}^{t} v_s dW_s^*, \quad (4)$$

7 It is also useful in developing the theory for realized autocovariance under a Brownian motion, which is important in the theory of realized kernels developed by Barndorff-Nielsen, Hansen, Lunde, and Shephard (2008).
Here $a^*, \sigma^*, \nu^*$ are adapted càdlàg processes, with $a^*$ also being predictable and locally bounded. $W^*$ is a Brownian motion independent of $W$.

(H2) $\sigma_t^2 > 0$ everywhere.

The assumption (H1) is rather general from an econometric viewpoint as it allows for flexible leverage effects, multifactor volatility effects, jumps, nonstationarities, intraday effects, etc. Indeed we do not know of a continuous time continuous sample path volatility model used in financial economics that is outside this class. Kinnebrock and Podolskij (2008) also allow jumps in the volatility under the usual (in this context) conditions introduced by Barndorff-Nielsen, Graversen, Jacod, Podolskij, and Shephard (2006) and discussed by, for example, Barndorff-Nielsen, Graversen, Jacod, and Shephard (2006) but we will not detail this here.

The assumption (H2) is also important, it rules out the situation where the diffusive component disappears.

**Proposition 2** Suppose (1), (H1) and (H2) holds, then

\[
\sqrt{n} \left\{ \sum_{i=1}^{[nt]} \begin{cases} y_i^2 \mathbb{1}_{\{y_i \geq 0\}} \\ y_i^2 \mathbb{1}_{\{y_i \leq 0\}} \end{cases} - \int_0^t \sigma_s^2 ds \begin{pmatrix} \frac{1}{2} \\ \frac{1}{2} \end{pmatrix} \right\} \xrightarrow{D} V_t
\]

where

\[
V_t = \int_0^t \alpha_s (1) ds + \int_0^t \alpha_s (2) dW_s + \int_0^t \alpha_s (3) dW'_s,
\]

\[
\alpha_s (1) = \frac{1}{\sqrt{2\pi}} \begin{pmatrix} 2a_s \sigma_s + \sigma_s \sigma^* \\ -1 \end{pmatrix},
\]

\[
\alpha_s (2) = \frac{2}{\sqrt{2\pi}} \sigma_s^2 \begin{pmatrix} 1 \\ -1 \end{pmatrix},
\]

\[
A_s = \begin{pmatrix} \frac{5}{4} & -\frac{1}{4} \\ \frac{1}{4} & \frac{1}{4} \end{pmatrix},
\]

\[
\alpha_s (3)' = A_s - \alpha_s (2) \alpha_s (2)',
\]

where $\alpha_s (3)$ is a $2 \times 2$ matrix. Here $W'$ is independent of $(W, W^*)$, the Brownian motion which appears in the Brownian semimartingale (1) and (H1).

**Proof** Given in the Appendix.

**Remark 2** When we look at

\[
RV = (1, 1) \sum_{i=1}^{[nt]} \begin{pmatrix} y_i^2 \mathbb{1}_{\{y_i \geq 0\}} \\ y_i^2 \mathbb{1}_{\{y_i \leq 0\}} \end{pmatrix},
\]
then we produce the well-known result
\[ \sqrt{n} \left( RV - \int_0^t \sigma_s^2 \, ds \right) \overset{D}{\to} \int_0^t 2\sigma_s^2 \, dW_s' \]
which appears in Jacod (1994) and Barndorff-Nielsen and Shephard (2002).

**Remark 3** Assume \( a, \sigma \perp W \) then
\[ \sqrt{n} \left\{ \sum_{i=1}^{\lfloor nt \rfloor} \left( \frac{y_i^2 1_{y_i \geq 0}}{y_i^2} \right) - \frac{1}{2} \int_0^t \sigma_s^2 \, ds \, \left( \begin{array}{c} 1 \\ 1 \end{array} \right) \right\} \overset{D}{\to} MN \left( \frac{1}{\sqrt{2\pi}} \int_0^t \{2a_s \sigma_s + \sigma_s \sigma_s^*\} \, ds \, \left( \begin{array}{c} 1 \\ -1 \end{array} \right), \frac{1}{4} \int_0^t \sigma_s^4 \, ds \, \left( \begin{array}{c} 5 \\ -1 \\ -1 \\ 5 \end{array} \right) \right). \]
If there is no drift and the volatility of volatility was small then the mean of this mixed Gaussian distribution is zero and we could use this limit result to construct confidence intervals on these quantities. When the drift is not zero we cannot use this result as we do not have a method for estimating the bias which is a scaled version of
\[ \frac{1}{\sqrt{n}} \int_0^t \{2a_s \sigma_s + \sigma_s \sigma_s^*\} \, ds. \]
Of course in practice this bias will be small. The asymptotic variance of
\[ (1, -1) \sum_{i=1}^{\lfloor nt \rfloor} \left( \frac{y_i^2 1_{y_i \geq 0}}{y_i^2} \right) \]
is \( \frac{3}{n} \int_0^t \sigma_s^4 \, ds \), but obviously not mixed Gaussian.

**Remark 4** When the \( a, \sigma \) is independent of \( W \) assumption fails, we do not know how to construct confidence intervals even if the drift is zero. This is because in the limit
\[ \sqrt{n} \left\{ \sum_{i=1}^{\lfloor nt \rfloor} \left( \frac{y_i^2 1_{y_i \geq 0}}{y_i^2} \right) - \frac{1}{2} \int_0^t \sigma_s^2 \, ds \, \left( \begin{array}{c} 1 \\ 1 \end{array} \right) \right\} \]
depends upon \( W \). All we know is that the asymptotic variance is again
\[ \frac{1}{4n} \int_0^t \sigma_s^4 \, ds \left( \begin{array}{c} 5 \\ -1 \\ -1 \\ 5 \end{array} \right). \]
Notice, throughout the asymptotic variance of \( RS^- \) is
\[ \frac{5}{4n} \int_0^t \sigma_s^4 \, ds \]
so it is less than that of the RV (of course it estimates a different quantity). It also means the asymptotic variance of \( RS^+ - RS^- \) is
\[ \frac{3}{n} \int_0^t \sigma_s^4 \, ds. \]
Remark 5 We can look at the measure of the variation of negative jumps through
\[ \sqrt{n} \left( 2 \sum_{i=1}^{[nt]} y_i^2 1_{\{y_i \leq 0\}} - \frac{1}{\mu_t^2} \sum_{i=1}^{[nt]} |y_i| |y_{i-1}| \right) \to^D V_t \]
where
\[ V_t = \int_0^t \alpha_s(1) ds + \int_0^t \alpha_s(2) dW_s + \int_0^t \alpha_s(3) dW'_s, \]
\[ \alpha_s(1) = -2 \frac{1}{\sqrt{2\pi}} \left\{ 2a_s \sigma_s + \sigma_s \sigma^*_s \right\}, \]
\[ \alpha_s(2) = -2 \frac{2}{\sqrt{2\pi}} \sigma^2_s, \]
\[ A_s = \sigma^4_s \left( \mu_1^{-4} + 2 \mu_1^{-2} - 2 \right), \]
\[ \alpha_s(3) \alpha_s(3)' = A_s - \alpha_s(2) \alpha_s(2)'. \]
We note that
\[ \mu_1^{-4} + 2 \mu_1^{-2} - 2 \simeq 3.6089, \]
which is quite high (the corresponding term is about 0.6 when we look at the difference between realized variance and bipower variation). Without the assumption that the drift is zero and no leverage, it is difficult to see how to use this distribution as the basis of a test.

3. More empirical work

3.1. More on GE trade data

For the GE trade data, Table 7.2 reports basic summary statistics for squared open to close daily returns, realized variance and downside realized semivariance. Much of this is

Regression of returns $r_i$ on lagged realized semivariance $RS_{i-1}^{-}$ and returns $r_{i-1}$ for daily returns based on the GE trade database.

familiar, with the average level of squared returns and realized variance being roughly the same, whereas the mean of the downside realized semivariance is around one-half that of the realized variance. The most interesting results are that the $RS^{-}$ statistic has a correlation with RV of around 0.86 and that it is negatively correlated with daily returns. The former correlation is modest for an additional volatility measure and indicates that it may have additional information not in the RV statistic. The latter result shows that large daily semivariances are associated with contemporaneous downward moves in the asset price – which is not surprising of course.

The serial correlations in the daily statistics are also presented in Table 7.2. They show the RV statistic has some predictability through time, but that the autocorrelation in the $RS^{-}$ is much higher. Together with the negative correlation between returns and contemporaneous $RS^{-}$ (which is consistent for a number of different assets), this suggests one should be able to modestly predict returns using past $RS^{-}$.

Table 7.3 shows the regression fit of $r_i$ on $r_{i-1}$ and $RS_{i-1}^{-}$ for the GE trade data. The t-statistic on lagged $RS^{-}$ is just significant and positive. Hence a small amount of the variation in the high-frequency falls of price in the previous day are associated with rises in future asset prices – presumably because the high-frequency falls increase the risk premium. The corresponding t-statistics for the impact of $RS_{i-1}^{-}$ for other series are given in Table 7.6, they show a similar weak pattern.

The $RS^{-}$ statistic has a similar dynamic pattern to the bipower variation statistic. The mean and standard deviation of the $RS^{-}$ statistic is slightly higher than half the realized BPV one. The difference estimator

$$BPDV_i = RS_i^{-} - 0.5BPV_i,$$

which estimates the squared negative jumps, is highly negatively correlated with returns but not very correlated with other measures of volatility. Interestingly this estimator is slightly autocorrelated, but at each of the first 10 lags this correlation is positive, which means it has some forecasting potential.

---

8This is computed using not one but two lags, which reduces the impact of market microstructure, as shown by Andersen, Bollerslev, and Diebold (2007).

Summary statistics for various daily data computed using trade data. $r_i$ denotes daily open to close returns, $RV_i$ is the realized variance, $RS_i$ is the realized semivariance, and $BPV_i$ is the daily realized bipower variation. $BPDV_i$ is the realized bipower downward variation statistic.

3.2. Other trade data

Results in Table 7.4 show that broadly the same results hold for a number of frequently traded assets – American Express (AXP), Walt Disney (DIS) and IBM. Table 7.5 shows the log-likelihood improvements$^9$ by including RV and $RS^c$ statistics into the GARCH and GJR models based on trades. The conclusion is clear for GARCH models. By including $RS^c$ statistics in the model there is little need to include a traditional leverage effect. Typically it is only necessary to include $RS^c$ in the information set, adding RV plays only a modest role. For GJR models, the RV statistic becomes more important and is sometimes slightly more effective than the $RS^c$ statistic.

$^9$Of course the log-likelihoods for the ARCH-type models are Gaussian quasi-likelihoods and so the standard distributional theory for likelihood ratios does not apply directly. Instead one can think of the model fit through a criteria like BIC.

Improvements in the Gaussian quasi-likelihood by including lagged realized quantities in the conditional variance over standard GARCH and GJR models. Fit of GARCH and GJR models for daily open to close returns on four share prices, from 1995 to 2005. We allow lagged daily realized variance (RV), realized semivariance ($RS^-$), realized bipower variation (BPV) to appear in the conditional variance. They are computed using every 15th trade.

3.3. Quote data

We have carried out the same analysis based on quote data, looking solely at the series for offers to buy placed on the New York Stock Exchange. The results are given in Tables 7.6 and 7.7. The results are in line with the previous trade data. The $RS^-$ statistic is somewhat less effective for quote data, but the changes are marginal.

4. Additional remarks

4.1. Bipower variation

We can build on the work of Barndorff-Nielsen and Shephard (2004), Barndorff-Nielsen and Shephard (2006), Andersen, Bollerslev, and Diebold (2007) and Huang and Tauchen

Quote data: Improvements in the Gaussian quasi-likelihood by including lagged realized quantities in the conditional variance. Fit of GARCH and GJR models for daily open to close returns on four share prices, from 1995 to 2005. We allow lagged daily realized variance (RV) and realized semivariance (RS) to appear in the conditional variance. They are computed using every 15th trade.

(2005) by defining

\[ BPDV = \sum_{j=1}^{t_j \leq 1} (Y_{t_j} - Y_{t_j-1})^2 I_{Y_{t_j} - Y_{t_j-1} \leq 0} - \frac{1}{2} \mu_1^{-2} \sum_{j=2}^{t_j \leq 1} |Y_{t_j} - Y_{t_j-1}| |Y_{t_j-1} - Y_{t_j-2}| \]

and

\[ \frac{p}{n} \sum_{s \leq t} (\Delta Y_s)^2 I_{\Delta Y_s \leq 0}, \]

the realized bipower downward variation statistic (upward versions are likewise trivial to define). This seems a novel way of thinking about jumps – we do not know of any literature that has identified \( \sum_{s \leq t} (\Delta Y_s)^2 I_{\Delta Y_s \leq 0}, r > 2 \)

before. It is tempting to try to carry out jump tests based upon it to test for the presence of downward jumps against a null of no jumps at all. However, the theory developed in Section 2 suggests that this is going to be hard to implement based solely on in-fill asymptotics without stronger assumptions than we usually like to make due to the presence of the drift term in the limiting result and the nonmixed Gaussian limit theory (we could do testing if we assumed the drift was zero and there is no leverage term). Of course, it would not stop us from testing things based on the time series dynamics of the process – see the work of Corradi and Distaso (2006).

Further, a time series of such objects can be used to assess the factors that drive downward jumps, by simply building a time series model for it, conditioning on explanatory variables.

An alternative to this approach is to use higher order power variation statistics (e.g. Barndorff-Nielsen and Shephard, 2004 and Jacod, 2007),

\[ \sum_{j=1}^{t_j \leq 1} |Y_{t_j} - Y_{t_j-1}|^r I_{Y_{t_j} - Y_{t_j-1} \leq 0} \overset{p}{\to} \sum_{s \leq t} |\Delta Y_s|^r I_{\Delta Y_s \leq 0}, \quad r > 2, \]

as \( n \to \infty \). The difficulty with using these high order statistics is that they will be more sensitive to noise than the BPDV estimator.
5 Conclusions

4.2. Effect of noise

Suppose instead of seeing $Y$ we see $X = Y + U$, and think of $U$ as noise. Let us focus entirely on

$$
\sum_{i=1}^{n} x_i^2 \mathbb{1}_{\{x_i \leq 0\}} = \sum_{i=1}^{n} y_i^2 \mathbb{1}_{\{y_i \leq -u_i\}} + \sum_{i=1}^{n} u_i^2 \mathbb{1}_{\{u_i \leq -y_i\}} + 2 \sum_{i=1}^{n} y_i u_i \mathbb{1}_{\{y_i \leq -u_i\}}
$$

$$
\simeq \sum_{i=1}^{n} y_i^2 \mathbb{1}_{\{u_i \leq 0\}} + \sum_{i=1}^{n} u_i^2 \mathbb{1}_{\{u_i \leq 0\}} + 2 \sum_{i=1}^{n} y_i u_i \mathbb{1}_{\{u_i \leq 0\}}.
$$

If we use the framework of Zhou (1996), where $U$ is white noise, uncorrelated with $Y$, with $E(U) = 0$ and $\text{Var}(U) = \omega^2$ then it is immediately apparent that the noise will totally dominate this statistic in the limit as $n \to \infty$.

Pre-averaging based statistics of Jacod, Li, Mykland, Podolskij, and Vetter (2007) could be used here to reduce the impact of noise on the statistic.

5. Conclusions

This chapter has introduced a new measure of variation called downside “realized semivariance.” It is determined solely by high-frequency downward moves in asset prices. We have seen it is possible to carry out an asymptotic analysis of this statistic and see that its limit is effects only by downward jumps.

We have assessed the effectiveness of this new measure using it as a conditioning variable for a GARCH model of daily open to close returns. Throughout, for nonleverage-based GARCH models, downside realized semivariance is more informative than the usual realized variance statistic. When a leverage term is introduced it is hard to tell the difference.

Various extensions to this work were suggested.

The conclusions that downward jumps seem to be associated with increases in future volatility is interesting for it is at odds with nearly all continuous time parametric stochastic volatility models. It could only hold, except for very contrived models, if the volatility process also has jumps in it and these jumps are correlated with the jumps in the price process. This is because it is not possible to correlate a Brownian motion process with a jump process. This observation points us towards models of the type, for example, introduced by Barndorff-Nielsen and Shephard (2001). It would suggest the possibilities of empirically rejecting the entire class of stochastic volatility models built solely from Brownian motions. This seems worthy of some more study.

Appendix: Proof of Proposition 2

Consider the framework of Theorem 2 in Kinnebrock and Podolskij (2008) and choose

$$
g(x) = \begin{pmatrix} g_1(x) \\ g_2(x) \\ g_3(x) \end{pmatrix} = \begin{pmatrix} x^2 \mathbb{1}_{\{x \geq 0\}} \\ x^2 \mathbb{1}_{\{x \leq 0\}} \\ |x| \end{pmatrix} \quad \text{and} \quad h(x) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & |x| \end{pmatrix}
$$
Assume that $X$ is a Brownian semimartingale, conditions (H1) and (H2) are satisfied and note that $g$ is continuously differentiable and so their theory applies directly. Due to the particular choice of $h$ we obtain the stable convergence

$$\sqrt{n} \left\{ V(Y,n) - \int_0^t \sigma_s^2 \frac{1}{2} \mu_s^2 (\frac{1}{2}) \right\} \xrightarrow{\mathbb{P}} \int_0^t \alpha_s(1) ds + \int_0^t \alpha_s(2) dW_s + \int_0^t \alpha_s(3) dW_s', \quad (5)$$

where $W'$ is a one-dimensional Brownian motion defined on an extension of the filtered probability space and independent of the $\sigma$-field $\mathcal{F}$. Using the notation

$$\rho_\sigma (g) = \mathbb{E} \{ g(\sigma U) \}, \quad U \sim N(0,1)$$

$$\rho_\sigma^{(1)} (g) = \mathbb{E} \{ Ug(\sigma U) \}, \quad U \sim N(0,1)$$

$$\tilde{\rho}_\sigma^{(1,1)} (g) = \mathbb{E} \left\{ g(\sigma W_1) \int_0^1 W_s dW_s \right\},$$

the $\alpha(1), \alpha(2)$ and $\alpha(3)$ are defined by

$$\alpha_s (1)_j = \sigma_s^* \tilde{\rho}_\sigma^{(1,1)} \left( \frac{\partial g_j}{\partial x} \right) \rho_\sigma (h_{jj}) + a_s \rho_\sigma (g_j) \rho_\sigma (h_{jj})$$

$$\alpha_s (2)_j = \rho_\sigma^{(1)} (g_j) \rho_\sigma (h_{jj})$$

$$\alpha_s (3) \alpha_s (3)' = A_s - \alpha_s (2) \alpha_s (2)'$$

and the elements of the $3 \times 3$ matrix process $A$ is given by

$$A_{s,j,j'}^s = \rho_\sigma (g_j g_{j'}) \rho_\sigma (h_{jj} h_{jj'}) + \rho_\sigma (g_j) \rho_\sigma (g_{j'} h_{jj}) \rho_\sigma (h_{j'j})$$

$$+ \rho_\sigma (g_j) \rho_\sigma (g_{j'}) \rho_\sigma (h_{jj}) \rho_\sigma (h_{j'j'})$$

$$- 3 \rho_\sigma (g_j) \rho_\sigma (g_{j'}) \rho_\sigma (h_{jj}) \rho_\sigma (h_{j'j'}).$$

Then we obtain the result using the following Lemma.

**Lemma 1** Let $U$ be standard normally distributed. Then

$$\mathbb{E} \left[ 1_{\{ U \geq 0 \}} \right] = \frac{2}{\sqrt{2\pi}}, \quad \mathbb{E} \left[ 1_{\{ U \leq 0 \}} \right] = \frac{1}{\sqrt{2\pi}},$$

$$\mathbb{E} \left[ 1_{\{ U \geq 0 \}} \right] = \frac{-2}{\sqrt{2\pi}}, \quad \mathbb{E} \left[ 1_{\{ U \leq 0 \}} \right] = -\frac{1}{\sqrt{2\pi}}.$$

**Proof** Let $f$ be the density of the standard normal distribution.

$$\int_0^\infty f(x) dx = \frac{1}{\sqrt{2\pi}} \int_0^\infty \exp \left( -\frac{x^2}{2} \right) dx$$

$$= \frac{1}{\sqrt{2\pi}} \left[ -\exp \left( -\frac{x^2}{2} \right) \right]_0^\infty$$

$$= \frac{1}{\sqrt{2\pi}}.$$
5 Conclusions

Using partial integration we obtain
\[
\int_0^\infty f(x) \, dx = \frac{1}{\sqrt{2\pi}} \int_0^\infty \frac{x^2}{\sqrt{\pi}} \exp \left( -\frac{x^2}{2} \right) \, dx
\]
\[
= \frac{1}{\sqrt{2\pi}} \left[ \frac{1}{2} x^2 \exp \left( -\frac{x^2}{2} \right) \right]_0^\infty
\]
\[
- \frac{1}{\sqrt{2\pi}} \int_0^\infty \frac{1}{2} x^2 \left( \exp \left( -\frac{x^2}{2} \right) \right) \, dx
\]
\[
= \frac{1}{2\sqrt{2\pi}} \int_0^\infty \exp \left( -\frac{x^2}{2} \right) \, dx
\]
\[
= \frac{1}{2} \int_0^\infty x^3 f(x) \, dx.
\]

Thus
\[
\int_0^\infty x^3 f(x) \, dx = \frac{2}{\sqrt{2\pi}}.
\]

Obviously, it holds
\[
\int_{-\infty}^0 f(x) \, dx = -\int_0^\infty f(x) \, dx,
\]
\[
\int_{-\infty}^0 x^3 f(x) \, dx = -\int_0^\infty x^3 f(x) \, dx.
\]

This completes the proof of the Lemma.

Using the lemma we can calculate the moments
\[
\rho_{\sigma_x}(g_1) = \rho_{\sigma_x}(g_2) = \frac{1}{2} \sigma_s^2,
\]
\[
\rho_{\sigma_x}(h_{1,1}) = \rho_{\sigma_x}(h_{2,2}) = 1,
\]
\[
\rho_{\sigma_x}(h_{3,3}) = \rho_{\sigma_x}(g_3) = \mu_1 \sigma_s,
\]
\[
\rho_{\sigma_x}^{(1)}(g_1) = \frac{2}{\sqrt{2\pi}} \sigma_s^2 = -\rho_{\sigma_x}^{(1)}(g_2),
\]
\[
\rho_{\sigma_x}(g_1h_{3,3}) = \rho_{\sigma_x}(g_2h_{3,3}) = \frac{1}{2} \sigma_s^2 \mu_3,
\]
\[
\rho_{\sigma_x}(g_3h_{3,3}) = \mu_1^2 \sigma_s^2, \rho_{\sigma_x}(g_3^2) = \rho_{\sigma_x}(h_3^3) = \mu_1^2.
\]

We note that \( \mu_3 = 2\mu_1 \). Further
\[
\rho_{\sigma_x} \left( \frac{\partial g_1}{\partial x} \right) = \frac{2}{\sqrt{2\pi}} \sigma_s = -\rho_{\sigma_x} \left( \frac{\partial g_2}{\partial x} \right),
\]
Measuring downside risk – realized semivariance

\[ \rho_{\sigma_s}^{(1)} \left( \frac{\partial g_1}{\partial x} \right) = \rho_{\sigma_s}^{(1)} \left( \frac{\partial g_2}{\partial x} \right) = \sigma_s, \]

\[ \rho_{\sigma_s} \left( (g_1)^2 \right) = \rho_{\sigma_s} \left( (g_2)^2 \right) = \frac{3}{2} \sigma_s^4, \]

\[ \rho_{\sigma_s}^{11} \left( \frac{\partial g_1}{\partial x} \right) = \frac{\sigma_s}{\sqrt{2\pi}} \rho_{\sigma_s}^{11} \left( \frac{\partial g_2}{\partial x} \right). \]

The last statement follows from

\[ \rho_{\sigma_s} \left( \frac{\partial g_1}{\partial x} \right) = E \left[ \frac{\partial g_1}{\partial x} (\sigma_s W_1) \int_0^1 W_u dW_u \right] \]

\[ = 2E \left[ \sigma_s W_1 1_{\{W_1 \geq 0\}} \int_0^1 W_u dW_u \right] \]

\[ = 2E \left[ \sigma_s W_1 1_{\{W_1 \geq 0\}} \left( \frac{1}{2} W_1^2 - \frac{1}{2} \right) \right] \]

\[ = \sigma_s E \left[ (W_1^3 - W_1) 1_{\{W_1 \geq 0\}} \right] \]

\[ = \frac{\sigma_s}{\sqrt{2\pi}}. \]
